CIPROXIN® I.V. FLEXIBAG - ABRIDGED PRESCRIBING INFORMATION (Refer to Summary of Product Charac-teristics before prescribing). **Qualitative and Quantitative Composition:** One flexible infusion bag containing the equivalent of 200mg ciprofloxacin USP in 100ml, or 400mg ciprofloxacin USP in 200ml. **Pharmaceutical Form:** Solution for intravenous infusion. **Therapeutic Indications:** Ciprofloxacin is indicated for the treatment of infections caused by susceptible organisms. Refer to summary of product characteristics for microbiological activity. **Posology and Method of Administration:** ***Adults*** 100-400mg administered intravenously over 30 to 60 minutes. The 400mg dose should be administered over a period of 60 minutes. Initial intravenous administration may be followed by oral treatment. *Impaired renal function* Dosage adjustment not usually required except in severe renal impairment. Reduce total daily dose by half, or adjust dose on basis of drug serum levels. *Elderly and hepatic impairment* No dose adjustment. *Adolescents and children* Not recommended. However, where potential benefit outweighs the risk, a dose of 5-10mg/kg/day in two divided doses should be used. **Duration of Treatment:** For acute infections, the usual treatment period is 5 to 7 days. Generally, in acute and chronic infections where sensitivity is proven, treatment should be continued for at least 3 days after the signs and symptoms of infection have disappeared. **Contra-Indications:** Hypersensitivity to ciprofloxacin or other quinolones; also in children and growing adolescents except where the benefits of treatment outweigh the risks. **Special Warnings and Precautions for Use:** Use with caution in epileptics and patients with a history of CNS disorders. Crystalluria has been reported so patients should be well hydrated and excessive urine alkalinity avoided. As haemolytic reactions with ciprofloxacin are possible in patients with a family history of, and actual defects in, glucose-6-phosphate dehydrogenase activity, use with caution. Tendon inflammation and rupture may occur, particularly in older patients and in those treated concurrently with corticosteroids. If seen, advise patient to discontinue Ciproxin and rest limb(s). **Interactions with other Medicaments and other Forms of Interaction:** Increased plasma levels of theophylline have been observed following concurrent administration with ciprofloxacin. The dose of theophylline should be reduced and plasma levels of theophylline monitored. Where monitoring of plasma levels is not possible, avoid the use of ciprofloxacin in patients receiving theophylline. Particular caution is advised in those patients with convulsive disorders. Interactions have also been noted with anticoagulants and cyclosporin. High doses of quinolones have shown an interaction with NSAIDs in animals leading to convulsions. Administration of quinolones and glibenclamide simultaneously can potentiate the effect of glibenclamide, resulting in hypoglycaemia. Concomitant use with probenecid reduces the renal clearance of ciprofloxacin, so increasing serum levels. **Pregnancy and Lactation:** Not recommended. **Effects on Ability to Drive and use Machines:** Ciprofloxacin could result in impairment of the patientis ability to drive or operate machinery, particularly in conjunction with alcohol. **Undesirable Effects:** Local irritation at site of injection. Gastro-intestinal, CNS, hypersensitivity/skin reactions, musculoskeletal and special sense disturbances. Renal and hepatic disturbances. Effects on haematological parameters. Also reported: tachycardia. **Overdose:** Reversible renal toxicity has occurred. Monitor renal function and acidify if required to prevent crystalluria. Keep patients well hydrated. Reduce serum levels by dialysis. **Legal Category:** POM. **Package Quantities and Basic NHS Costs:** Flexible PVC bags, containing 100ml or 200ml of solution in packs of 10: 100ml £208.50 200ml £304.50. Marketing Authorisation Number: PL 0010/0220. **Date of Preparation:** March 1997. Further information available from: Bayer plc, Pharmaceutical Division, Bayer House, Strawberry Hill, Newbury, Berkshire RG14 1JA. Telephone: (01635) 563000.

The *British Journal of Surgery*

Published on behalf of the British Journal of Surgery Society. All queries regarding submitted papers not yet accepted for publication should be addressed to:

Joint Editors, *British Journal of Surgery*, Blackwell Science Ltd, 25 John Street, London WC1N 2BL, UK (Tel: + 44 171 404 1831).

Manager	Elizabeth Whelan
Production Editor	Alison Cherrie, e-mail: bjs@blacksci.co.uk
Editorial Controller	Emma Lawrence
Editorial Secretary	Clare Lack

Aims and scope

The *British Journal of Surgery* is the premier general surgical journal in Europe and one of the top surgical periodicals in the world. Its international readership is reflected in the prestigious International Editorial Board, supported by a panel of over 900 reviewers worldwide.

The *British Journal of Surgery* features the very best in clinical and laboratory-based research on all aspects of general surgery and related topics. Developing areas such as minimally invasive therapy and interventional radiology are strongly represented.

The inclusion of Leading Articles, Reviews, Original Articles, and articles 'For Debate' means that the *British Journal of Surgery* offers an appropriate format for any length or type of submission; in addition, there are abstracts from key meetings, correspondence, book reviews, conference dates and regular digests by the European Editor of the contents of other major journals. The *British Journal of Surgery* will be of interest not only to general surgeons, but also to specialty surgeons and those working in related fields.

Subscriptions

The *British Journal of Surgery* is published monthly (one volume per annum) in 1998. Subscription prices for 1998 are:

	EUROPE	OVERSEAS	NORTH AMERICA
Institutional	£122.00	£137.00	$227.50
Individual	£79.00	£90.00	$149.50

Subscribers in Canada must add 7% to the subscription price to allow for GST. Subscribers in Europe must quote their VAT registration number or state that they are not registered. Subscribers in the following countries who are not VAT-registered must add VAT at the appropriate rate:

Belgium (6% TVA/BTW)
France (2.1% TVA)
Germany (7% MWST)
Spain (4% IVA)
The Netherlands (6% BTW)

Orders for current subscriptions and back issues should be sent to Blackwell Science Ltd, Journal Subscriptions, PO Box 88, Oxford OX2 0NE, UK. Tel: +44 1865 206180 or 206038; Fax: +44 1865 206219; e-mail: journals.cs@blacksci.co.uk

Despatch

The *British Journal of Surgery* is despatched within the UK by second class post, within Europe by air mail, and to other continents by various forms of air-speeded delivery, to the USA by air freight for forwarding by second class post*, to India by air freight for guaranteed local delivery, and to all other countries by accelerated surface post. Add to the cost of a regular subscription £24.00/$36.00 for air mail delivery outside Europe.

Business correspondence

All other business correspondence, including orders for offprints (offprints@blacksci.co.uk) and advertising space (advert@blacksci.co.uk) should be addressed to:

The *British Journal of Surgery*, Blackwell Science Ltd, Osney Mead, Oxford OX2 0EL, UK. (Tel: +44 1865 206206; Fax: +44 1865 721205).

The British Journal of Surgery

VOLUME 85 NUMBER 4 APRIL 1998

Contents

Leading article

433 **Cancer surgery: why some survival benefits may be artefactual**
D. M. Dent
A warning lest we delude ourselves

Reviews

435 **Endoluminal abdominal aortic aneurysm surgery**
K. R. Woodburn, J. May and G. H. White
Concern remains about the long-term outcome of endoluminal surgery

444 **Lymphocyte function in wound healing and following injury**
M. Schäffer and A. Barbul
Consideration should be given to modulation of immune function following injury

461 **Non-operative management of blunt hepatic trauma**
E. H. Carrillo, A. Platz, F. B. Miller, J. D. Richardson and H. C. Polk Jr
With careful monitoring, non-operative management is safe in haemodynamically stable patients

469 **Early colorectal cancer: recognition, classification and treatment**
K. S. Mainprize, N. J. McC. Mortensen and B. F. Warren
Increasing numbers of early colorectal cancers are being recognized

Digest

477 *Annales de Chirurgie*
D. Castaing

Original articles

480 **Circulating bile is the main factor responsible for atrial natriuretic peptide release in experimental obstructive jaundice**
F. Martínez-Ródenas, J. A. Pereira, W. Jiménez, J. M. Gubern and A. Sitges-Serra
Changes in biliary pressure or duodenal bile content are not the cause

485 **Total vascular exclusion of the liver for the resection of lesions in contact with the vena cava or the hepatic veins**
T. Berney, G. Mentha and Ph. Morel
Morbidity is not increased provided the 1-h time limit is observed

489 **Prospective randomized trial of systemic antibiotics in patients undergoing liver resection**
C.-C. Wu, D.-C. Yeh, M.-C. Lin, T.-J. Liu and F.-K. P'Eng
Prophylactic antibiotics are ineffective in preventing infective complications after liver resection

494 **Encouraging results of split-liver transplantation**
D. F. Mirza, O. Achilleos, J. Pirenne, J. A. C. Buckels, P. McMaster and A. D. Mayer
May improve utilization of a scarce resource

498 **Carcinoma of the head of the pancreas arising from the uncinate process**
D. Birk, M. H. Schoenberg, F. Gansauge, A. Formentini, G. Fortnagel and H. G. Beger
Presents at a later stage, with a worse prognosis than at other sites in the head

502 **Raised endothelin 1 levels in patients with colorectal liver metastases**
A. Shankar, M. Loizidou, G. Aliev, S. Fredericks, D. Holt, P. B. Boulos, G. Burnstock and I. Taylor
Endothelin 1 levels are raised but unfortunately do not serve either as a tumour marker or staging marker in patients with colorectal cancer

507 **Carotid endarterectomy is safe in selected elderly patients** (short note)
M. Pemberton, A. Reid, N. J. M. London, P. R. F. Bell and A. R. Naylor
The rate of death or disabling stroke was 2·6 per cent in the 235 patients over 70 years reported here

508 **Trials and tribulations of vascular surgical benchmarking**
D. C. Berridge, D. J. A. Scott, J. D. Beard and L. Hands
It is not safe to compare hospital performance directly until the methodology is more robust

Original articles (continued)

511 **Cryopreserved aortic homografts for patients who need simultaneous aortic and gastrointestinal surgery** (surgical workshop)
P. R. Vogt, D. Candinas, M. Genoni, G. Zünd, R. Schlumpf and M. I. Turina
A return to methods first used in the 1950s for aortic reconstruction

512 **Ruptured hepatocellular carcinoma as a complication of transarterial oily chemoembolization**
C.-L. Liu, H. Ngan, C. M. Lo and S. T. Fan
Rupture occurs rarely, after first treatment of large irresectable tumours in men

515 **Improved survival in patients with rectal cancer: a population-based register study**
M. Dahlberg, L. Påhlman, R. Bergström and B. Glimelius
At last survival rates from rectal cancer are improving

520 **Local anal hypothermia with a frozen finger: a treatment for acute painful prolapsed piles** (short note)
Y. El Ashaal, V. Prem Chandran, M. N. Siddiqui and A. J. W. Sim
An inexpensive and useful device

521 **Significance of local recurrence of rectal cancer as a local or disseminated disease**
S. Maetani, H. Onodera, T. Nishikawa, H. Morimoto, K. Ida, the late O. Kitamura and M. Imamura
Local recurrence is a manifestation of systemic disease

526 **Effect of the introduction of total mesorectal excision for the treatment of rectal cancer**
E. Carlsen, E. Schlichting, I. Guldvog, E. Johnson and R. J. Heald
This change initially increased the rate of anastomotic dehiscence

530 **Abdominal ultrasonography in the diagnosis of colonic cancer**
N. G. B. Richardson, A. G. Heriot, D. Kumar and A. E. A. Joseph
Useful diagnostic tool in the frail and elderly

534 **Influence of blood components and faeces on the *in vitro* cancericidal activity of povidone–iodine**
G. Basha, F. Penninckx and P. Yap
Contamination reduces cytotoxic activity especially at low concentrations

538 **Histamine in human breast cancer**
J. L. Reynolds, J. A. Akhter, C. J. Magarey, P. Schwartz, W. J. Adams and D. L. Morris
Histamine levels are increased but could that cause local immunosuppression?

542 **Long-term beneficial effects of a gastric reservoir on weight control after total gastrectomy: a study of potential mechanisms**
B. Liedman, I. Bosaeus, I. Hugosson and L. Lundell
Body composition is better preserved with a neo-stomach

548 **Relation between tumour necrosis factor α and interleukin 1β producing capacity of peripheral monocytes and pulmonary complications following oesophagectomy**
T. Katsuta, T. Saito, Y. Shigemitsu, T. Kinoshita, N. Shiraishi and S. Kitano
Raised monocyte carrying capacity of TNF-α and IL-1β was associated with postoperative pneumonia

554 **Vascular Surgical Society of Great Britain and Ireland Abstracts**

570 **Correspondence**

573 **Book reviews**

THE CHOICE
FOR PRECISION
WORLDWIDE

Swann-Morton's extra special "FINE' range began in response to advanced techniques involving precise and delicate surgery. The extended range now incorporates cylindrical handles in four lengths and a range of small, slim blades, manufactured in stainless steel with all the company's usual attention to fine detail. All appropriate products are sterilised by Swann-Morton (Services) Ltd.

Renowned for precision and excellence among the world's surgeons, every blade is subject to rigid and continual quality control procedures. As well as achieving BS5750, subsequently updated to BS EN ISO 9001, Swann-Morton have now been accredited to EN 46001, which enables them to CE mark their products under the Medical Device Directive (93/42/EEC).

ASGBI Book of Abstracts *Edinburgh 13 - 15 May 1998*
Published together with the June issue of the
British Journal of Surgery

In association with the *Association of Surgeons of Great Britain & Ireland Annual Meeting* and exhibition in Edinburgh, *Blackwell Science* will be publishing the ***Book of Abstracts***. Not only will each subscriber to the ***British Journal of Surgery*** receive a copy but also each attendee will have a copy inserted into their delegate wallet.

Subscriber copies will be despatched prior to the meeting so why not publicise your attendance at the exhibition by adding your stand number to the advertisement?

BOOKING DEADLINE: 21 April 1998 ◆ COPY DEADLINE: 28 April 1998

Blackwell Science

The British Journal of Surgery

VOLUME 85 NUMBER 5 MAY 1998

Contents

Leading articles

577 **Cystic tumours of the pancreas**
J. Le Borgne
Classification and treatment are discussed; some unanswered questions remain

580 **Skull radiographs and children with blunt head injury**
D. A. Lloyd
The significance of skull fracture is discussed and medicolegal concerns acknowledged

Reviews

582 **Antibiotic prophylaxis in the initial management of severe acute pancreatitis**
J. J. Powell, R. Miles and A. K. Siriwardena
Current experimental evidence favours the use of prophylactic antibiotics in severe acute pancreatitis

588 **Diagnosis and treatment of sphincter of Oddi dysfunction**
G. Tzovaras and B. J. Rowlands
Endoscopic and surgical treatments produce similar outcomes with substantial failure rates

596 **Recent advances in the surgical treatment of faecal incontinence**
C. J. Vaizey, M. A. Kamm and R. J. Nicholls
Successful treatment depends on accurate characterization of the pathology

Original articles

604 **Simple laparoscopic gastropexy as the initial treatment of paraoesophageal hiatal hernia**
A. O. Agwunobi, J. Bancewicz and S. E. A. Attwood
A useful option in high-risk patients

607 **Pancreatic cancer resection in elderly patients**
V. Di Carlo, G. Balzano, A. Zerbi and E. Villa
Older patients can withstand resection, with as much benefit as younger ones

611 **Survival following pancreaticoduodenectomy with resection of the superior mesenteric–portal vein confluence for adenocarcinoma of the pancreatic head**
S. D. Leach, J. E. Lee, C. Charnsangavej, K. R. Cleary, A. M. Lowy, C. J. Fenoglio, P. W. T. Pisters and D. B. Evans
If the superior mesenteric artery is involved, don't do it

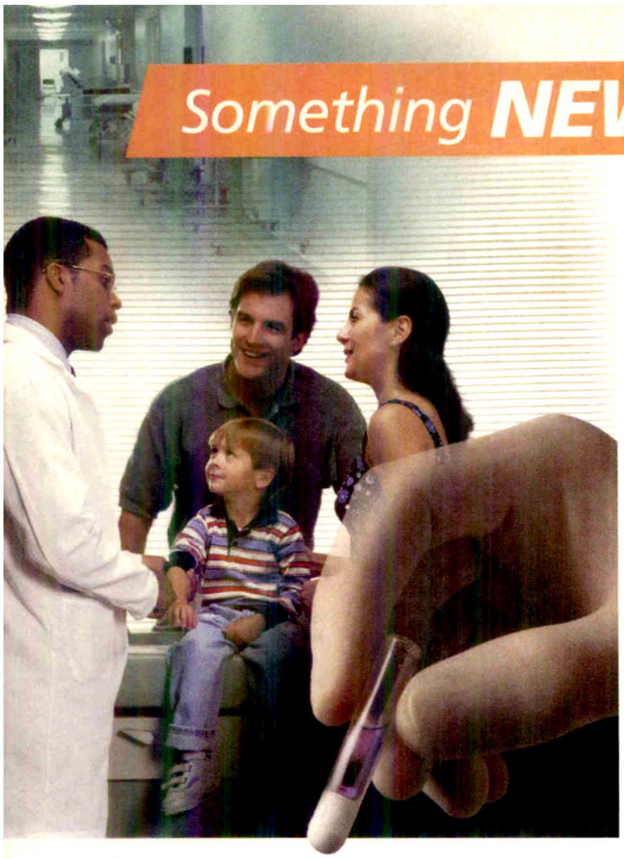
618 **Experimental study of a novel phospholipase A_2 inhibitor in acute pancreatitis**
W. Uhl, H.-J. Schrag, N. Schmitter, J. Aufenanger, T. J. Nevalainen and M. W. Büchler
The inhibitor reduced pancreatic damage and might be useful in patients with acute pancreatitis

624 **Laparoscopic cholangiography: a prospective study**
A. J. Sabharwal, E. J. Minford, L. P. Marson, I. M. Muir, D. Hill and C. D. Auld
Image intensifier required for the preferred technique

627 **Multidisciplinary approach to biliary complications of laparoscopic cholecystectomy**
N. Doctor, J. S. Dooley, R. Dick, A. Watkinson, K. Rolles and B. R. Davidson
Careful assessment and selection of treatment type can give good results

633 **Mortality following elective infrarenal aortic reconstruction: a Joint Vascular Research Group study**
R. B. Galland
Cardiac complications are the most lethal, although the cause of death is often multiorgan failure

637 **Survey of changes in the provision of vascular surgical services in the Oxford Region over 5 years**
R. B. Galland and T. R. Magee
Appointing a consultant vascular surgeon increases the number of vascular reconstructions performed but may not reduce amputation rates



Something **NEW** in skin closure

Now secure skin closure can be a comforting experience

Introducing **NEW**

DERMABOND*

TOPICAL SKIN ADHESIVE

2-Octyl Cyanoacrylate

Liquid Wound Support That Holds Secure!

The strength of approximated, healed tissue at 7 days...in just minutes![1] Ideal for the face, trunk, and limbs.

Liquid Wound Support That Holds Tight!

Especially suited for simple lacerations.

Liquid Wound Support That Holds Beautifully!

Excellent cosmetic results. Less trauma - dries clear.

Liquid Wound Support That Holds Fast!

Ideal for the busy Accident and Emergency department, Plastics and General Theatres.

Liquid Wound Support That Patients Love!

Quells fear of the needle.

a Johnson & Johnson company

Original articles (continued)

641 **Role of magnetic resonance angiography for assessment of abdominal aortic aneurysm before endoluminal repair**
A. Nasim, M. M. Thompson, R. D. Sayers, J. R. Boyle, T. Hartshorne, A. R. Moody and P. R. F. Bell
Magnetic resonance angiography was the most useful preoperative investigation

645 **A 21-year experience of abdominal aortic aneurysm operations in Edinburgh**
A. W. Bradbury, D. J. Adam, K. R. Makhdoomi, W. P. Stuart, J. A. Murie, A. McL. Jenkins and C. V. Ruckley
Increasing workload but no improvement in outcome

648 **Population-based record linkage study of the incidence of abdominal aortic aneurysm in Western Australia in 1985–1994**
J. B. Semmens, P. E. Norman, M. M. D. Lawrence-Brown, A. J. Bass and C. D. J. Holman
Has the incidence of aneurysms peaked?

653 **Arteriovenous fistula using transposed basilic vein**
P. C. Butterworth, T. M. Doughman, T. J. Wheatley and M. L. Nicholson
Useful for secondary or tertiary vascular access

655 **Multimodality treatment in the control of deep musculoaponeurotic fibromatosis**
A. I. Skene, L. Barr, R. P. A'Hern, C. Fisher and J. Meirion Thomas
Once again, adequate primary surgery is the key to local disease control

659 **Anovestibular fistula to Bartholin's gland**
N. P. J. Cripps and J. M. A. Northover
Rare but curable

662 **Outcome following laparoscopic resection for colorectal cancer**
J. Psaila, S. H. Bulley, P. Ewings, J. P. Sheffield and R. H. Kennedy
Improved outcome in patients selected for laparoscopic surgery: but was it the selection process or the technique?

665 **Surgical treatment of severe duodenal polyposis in familial adenomatous polyposis**
C. Penna, N. Bataille, P. Balladur, E. Tiret and R. Parc
High-risk polyps in the duodenum may require pancreaticoduodenectomy

669 **Assessment of a scoring system for breast imaging**
N. A. Roche, R. M. Given-Wilson, V. A. Thomas and N. P. M. Sacks
Helps a radiologist to report mammograms and ultrasonographic scans for breast disease

673 **Effect of graft reperfusion on intracellular calcium levels in mononuclear leucocytes during human orthotopic liver transplantation**
S. M. Enright, R. Srinivasa and M. C. Bellamy
Further evidence about the mechanisms of reperfusion injury

676 **Association of Upper Gastrointestinal Surgeons of Great Britain and Ireland Abstracts**

677 **Experimental study of acid burden and acute oesophagitis**
K. G. Pursnani, M. A. Mohiuddin, K. R. Geisinger, G. Weinbaum, D. A. Katzka and D. O. Castell
Acid (pH <3), not pepsin, causes oesophageal injury

681 **Association between restriction fragment length polymorphism of the L-*myc* gene and susceptibility to gastric cancer**
K. Shibuta, M. Mori, M. Haraguchi, K. Yoshikawa, H. Ueo and T. Akiyoshi
May identify patients at risk

685 **Surgical Research Society Abstracts**

715 **Errata**

716 **Correspondence**

718 **Book reviews**

719 **Instructions to authors**

- live theatre demonstrations
- intensely practical programmes
- small group format
- MATTUS approved courses

Advanced Endoscopic Surgery - a 5 day lab based practical course for experienced endoscopic surgeons covering advanced skills such as endoscopic suturing techniques and internal and external knot tying. Fee £1400.
18th - 22nd May 1998, 6th - 10th July 1998, 14th - 18th September 1998

Ductal Calculi: The Laparoscopic Approach - a 2 day course on single stage management of choledocholithiasis at the time of laparoscopic cholecystectomy.

Thoracoscopic Sympathectomy - a 2 day course which covers the anatomy of the autonomic nerves, indications, instrumentation, safe access, anaesthetic implications and conduct of sympathectomy.

Laparoscopic Colorectal Course - a 2 day course aimed at giving the skills and confidence to develop clinically based colorectal laparoscopic surgery.

Practical Aspects of Laparoscopic Fundoplication - A 3 day lab based practical course covering the practical and clinical aspects of both partial and total laparoscopic fundoplication. *8th - 10th June 1998*

Endoscopic Skills Courses

SURGICAL SKILLS UNIT

Sir Alfred Cuschieri, Director of Surgical Skills Unit, University of Dundee

Foundations of Laparoscopic Surgery - A 5 day practical course designed for practitioners intending to introduce the laparoscopic approach to their institution. The course covers all the essential basic skills and safety procedures for laparoscopic operations such as laparoscopic cholecystectomy, diagnostic laparoscopy and laparoscopic appendectomy. While teaching techniques it also deals with financial and management issues. ***3rd - 7th August 1998***

Essentials of Laparoscopic Surgery - a 3 day intensely practical course designed for those starting to operate using a laparoscope. The course covers the essential skills and safety procedures for basic laparoscopic operations such as laparoscopic cholecystectomy or laparoscopic appendectomy.
15th - 17th June 1998, 5th - 7th October 1998, 23rd - 25th November 1998

Other specialist courses held in the unit include Basic Upper G.I Endoscopy, Colonoscopy, Upper G.I Therapeutic Endoscopy, Endoscopic Sinus Surgery, Middle Ear Surgery, Bronchoscopy & Oesophagoscopy, Percutaneous Tracheostomy, Video-laparoscopy for Gynaecologist and Diagnostic Therapeutic Video-hysteroscopy, Advanced Airways Technique, Laryngeal Courses.

These practical courses offer:

- experienced tutors
- specially designed tissue models
- small group tuition
- live theatre link (where possible)

cst

The Centre for Surgical Technologies from the
Katholieke Universiteit Leuven (Belgium)
recruits for employment
from 1/10/1998 and from 1/1/1999,

TWO RESEARCH FELLOWS
for its
Endoscopic Fetal Surgery Research Programme

Current research fields include:

- in utero surgical treatment of congenital diaphragmatic hernia
- in utero gene therapy
- in utero surgery on the umbilical cord and placenta
- fetal membrane repair mechanisms

You will be working with one or two colleague fellows, and coached by two research directors. Besides the experimental work, the fellow will have the opportunity to observe operative fetoscopies in the clinical unit at the university hospitals.

Your profile: pediatric surgeon, senior level of training but by preference postdoctoral. The minimum period is one academic year, which can be extended to maximum three years. Stipend is according to the level of qualification.

If you are interested send your C.V. and application to Hugo De Fraye, Centre for Surgical Technologies, Minderbroedersstraat 17, B-3000 LEUVEN - BELGIUM.

Phone xx-32 (16) 33 78 38 Fax xx-32 (16) 33 78 21
Email: cst@uz.kuleuven.ac.be - http://www.kuleuven.ac.be/cst

Reprints of articles for the healthcare industry

Reprints of articles in this journal can be purchased from Blackwell Science Ltd, for use by the healthcare industry. Relevant articles on your products, or therapeutic areas, can help your intended market as well as company colleagues.

Further details and quotations (on order quantities of 500 and above) for a fast efficient service can be obtained from:

Blackwell Science

The British Journal of Surgery

VOLUME 85 NUMBER 6 JUNE 1998

Contents

Leading articles

721 **Venous insufficiency and perforating veins**
J. J. Bergan
Whatever the direction of blood flow, perforating veins may cause pathological damage

723 **Surgical treatment of anal incontinence**
C. G. M. I. Baeten
Many techniques have been tried over the years and the treatment is still evolving

Reviews

725 **Cytogenetics and the surgeon: an invaluable tool in diagnosis, prognosis and counselling of patients with solid tumours**
G. M. E. Humphrey, R. Squire, M. Lansdown, A. Markham and K. MacLennan
Cytogenetics may aid diagnosis when conventional histology shows no evidence of cellular differentiation

735 **Port-site metastases following laparoscopic surgery**
S. J. Neuhaus, M. Texler, P. J. Hewett and D. I. Watson
The incidence of wound metastasis is increased with the laparoscopic approach

742 **Upper gastrointestinal disease in patients with familial adenomatous polyposis**
M. H. Wallace and R. K. S. Phillips
The upper gastrointestinal tract is the commonest site of cancer after prophylactic colectomy

Original articles

751 **Results of pancreatogastrostomy after pancreatoduodenectomy in 160 consecutive patients**
J. M. Fabre, J. P. Arnaud, F. Navarro, R. Bergamaschi, C. Cervi, E. Marrel and J. Domergue
Pancreatogastrostomy is a safe procedure with few complications

755 **Percutaneous aspiration for bacteriological studies in patients with necrotizing pancreatitis**
F. Paye, N. Rotman, C. Radier, R. Nouira and P.-L. Fagniez
Surgery is often needed for drainage

760 **Co-existing biliary anomalies and anatomical variants in choledochal cyst**
T. Todani, Y. Watanabe, A. Toki, K. Ogura and Z.-O. Wang
Hilar anastomosis minimizes the risk of stricture formation and cholangitis

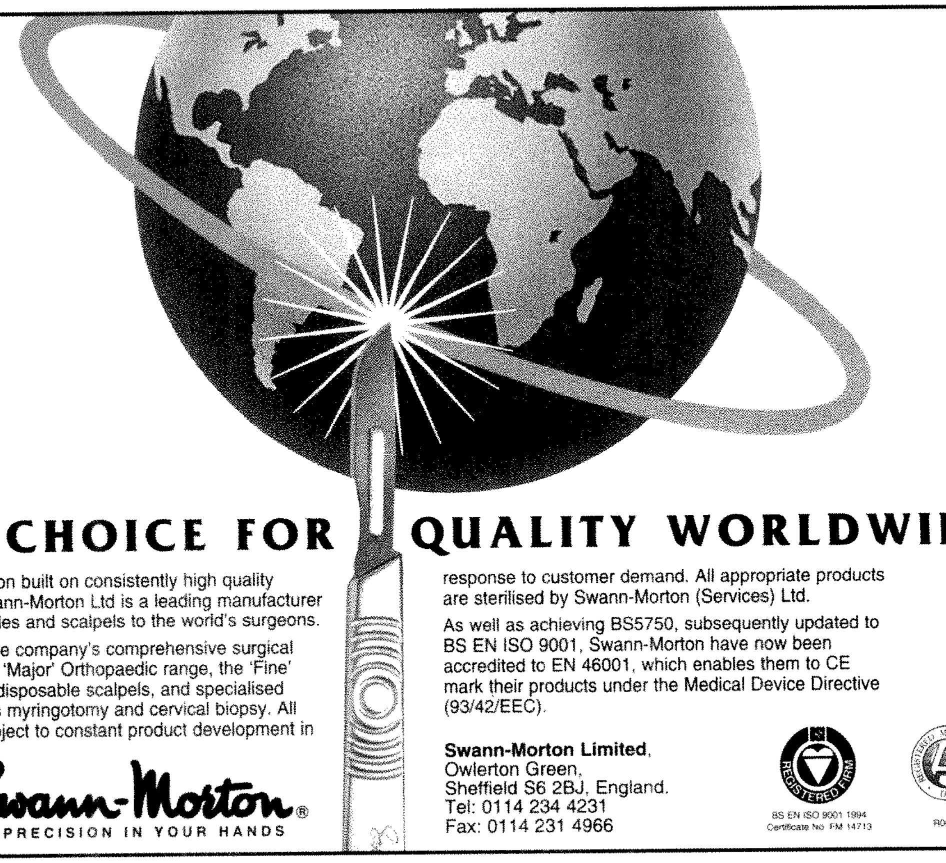
764 **Randomized trial of early *versus* delayed laparoscopic cholecystectomy for acute cholecystitis**
P. B. S. Lai, K. H. Kwong, K. L. Leung, S. P. Y. Kwok, A. C. W. Chan, S. C. S. Chung and W. Y. Lau
Early operation is better than delay: an open and closed case

768 **Role of arteriography in the selection of patients for carotid endarterectomy**
D. J. Bain, N. Fergie, R. O. Quin and M. Greene
A case for mandatory angiography before carotid endarterectomy

771 **Cerebral haemodynamics and embolization during carotid angioplasty in high-risk patients**
A. J. McCleary, M. Nelson, N. M. Dearden, T. A. J. Calvey and M. J. Gough
A less rosy view of carotid angioplasty

775 **Prospective randomized trial of woven *versus* collagen-impregnated knitted prosthetic Dacron grafts in aortoiliac surgery**
J. W. Quarmby, K. G. Burnand, S. J. M. Lockhart, A. E. Donald, K. M. Sommerville, C. W. Jamieson and N. L. Browse
No major clinical differences

778 **Results of aortic screening in the brothers of patients who had elective aortic aneurysm repair**
Y. van der Graaf, G. J. M. Akkersdijk, E. Hak, G. L. R. Godaert and B. C. Eikelboom
Until population screening programmes can be agreed the prevalence of 18 per cent in this study suggests that targetted screening is worthwhile



THE CHOICE FOR QUALITY WORLDWIDE

With a reputation built on consistently high quality standards, Swann-Morton Ltd is a leading manufacturer of surgical blades and scalpels to the world's surgeons.

Additional to the company's comprehensive surgical ranges are the 'Major' Orthopaedic range, the 'Fine' range, 'Minor' disposable scalpels, and specialised blades such as myringotomy and cervical biopsy. All ranges are subject to constant product development in response to customer demand. All appropriate products are sterilised by Swann-Morton (Services) Ltd.

As well as achieving BS5750, subsequently updated to BS EN ISO 9001, Swann-Morton have now been accredited to EN 46001, which enables them to CE mark their products under the Medical Device Directive (93/42/EEC).

Original articles (continued)

781 **Role of saphenous vein surgery in the treatment of venous ulceration**
J. M. Scriven, T. Hartshorne, A. J. Thrush, P. R. F. Bell, A. R. Naylor and N. J. M. London
Local anaesthetic saphenofemoral disconnection healed ulcers in patients with superficial venous disease alone

785 **Lower limb ischaemia–reperfusion injury causes endotoxaemia and endogenous antiendotoxin antibody consumption but not bacterial translocation**
M. M. I. Yassin, A. A. B. Barros D'Sa, T. G. Parks, C. V. Soong, M. I. Halliday, M. D. McCaigue, P. J. Erwin and B. J. Rowlands
Experimental study indicating that endotoxaemia may occur in limb ischaemia–reperfusion without evidence of infection or translocation

790 **Prospective randomized controlled trial to compare skin staples and polypropylene for securing the mesh in inguinal hernia repair**
I. W. Mills, I. M. McDermott and D. A. Ratliff
Staples significantly reduced the duration of hernia repair

793 **Lichtenstein inguinal hernia repair in a primary healthcare setting**
P. M. Lafferty, A. Malinowska and D. Pelta
Hernia repair does not require hospital premises

797 **Randomized placebo-controlled trial of local anaesthetic infusion in day-case inguinal hernia repair**
M. J. Oakley, J. S. Smith, J. R. Anderson and D. Fenton-Lee
50 h bupivacaine infusion reduced postoperative pain

800 **J ileal pouch–anal anastomosis for chronic ulcerative colitis: complications and long-term outcome in 1310 patients**
A. P. Meagher, R. Farouk, R. R. Dozois, K. A. Kelly and J. H. Pemberton
Surgical complications diminish but pouch failure rate increases with time

804 **Metabolic substrate utilization differs in ileal faecal and urinary reservoirs**
M. M. Duffy, M. C. Regan, M. G. Harrington, J. M. Fitzpatrick and P. R. O'Connell
Metabolic changes are associated with mucosal flora in ileal reservoirs and this may have an impact on mucosal integrity

809 **Extrafascial excision of the rectum for rectal cancer**
G. L. Hill and M. Rafique
Extrafascial resection minimizes local recurrence

813 **Novel approach to combined defaecation and micturition disorders with rectovaginovesicopexy**
R. Silvis, H. G. Gooszen, T. Kahraman, A. G. Groenendijk, M. T. W. T. Lock, M. V. Italiaander and L. W. M. Janssen
A pilot study charting a new course through difficult waters

818 **Proinflammatory mediator activity, endogenous antagonists and the systemic inflammatory response in intra-abdominal sepsis**
C. H. Wakefield, G. R. Barclay, K. C. H. Fearon, A. S. Goldie, J. A. Ross, I. S. Grant, G. Ramsay, J. C. Howie and the Scottish Sepsis Intervention Group
When organ failure develops the pattern of proinflammatory mediators and their endogenous antagonists can vary markedly

826 **Experimental study of adhesion formation in open and laparoscopic fundoplication**
L. Krähenbühl, M. Schäfer, V. Kuzinkovas, P. Renzulli, H. U. Baer and M. W. Büchler
Laparoscopic surgery induces fewer intraperitoneal adhesions but this is independent of TNF-α levels

831 **Ignoring small lymph nodes can be a major cause of staging error in gastric cancer**
N. Noda, M. Sasako, N. Yamaguchi and Y. Nakanishi
All nodes over 4 mm in size should be retrieved and examined

Tom Benson, Teacher's Pet

The British Journal of Surgery

VOLUME 85 NUMBER 7 JULY 1998

Contents

Leading article

881 **Split-liver transplantation**
M. Rela and N. D. Heaton
Split-liver transplantation represents a significant source of paediatric liver grafts, without compromising the adult donor pool

Reviews

884 **Metabolic response to severe injury**
A. G. Hill and G. L. Hill
Understanding metabolic response may lead to improved treatment for the critically ill

891 **Diet, reflux and the development of squamous cell carcinoma of the oesophagus in Africa**
A. M. Sammon and D. Alderson
A theory of causation is proposed

897 **Metachronous colorectal cancers**
O. Fajobi, C.-Y. Yiu, S. B. Sen-Gupta and P. B. Boulos
Preoperative colonoscopy and postoperative colonoscopic surveillance are essential in identifying patients at risk of metachronous colorectal cancer

Digest

902 *Der Chirurg*
Ch. Herfarth and Th. Lehnert

Original articles

904 **Laparoscopic subtotal cholecystectomy in patients with complicated acute cholecystitis or fibrosis**
K. Michalowski, P. C. Bornman, J. E. J. Krige, P. J. Gallagher and J. Terblanche
Subtotal cholecystectomy is a safe expedient to avoid injury during a difficult laparoscopic procedure

907 **Management of hepatobiliary and pancreatic *Ascaris* infestation in adults after failed medical treatment**
I. J. Beckingham, S. N. R. Cullis, J. E. J. Krige, P. C. Bornman and J. Terblanche
Endoscopy may help to avoid surgery when hepatopancreaticobiliary *Ascaris* is resistant to medical therapy

911 **Anomalous pancreaticobiliary junction without congenital choledochal cyst**
M. Sugiyama and Y. Atomi
Prophylactic cholecystectomy in all such patients will reduce the high (eight of 18) risk of cancer

917 **Follow-up of more than 10 years after endoscopic sphincterotomy for choledocholithiasis in young patients**
M. Sugiyama and Y. Atomi
About 10 per cent develop late complications

922 **Postoperative weight gain after standard Whipple's procedure *versus* pylorus-preserving pancreatoduodenectomy: the influence of tumour status**
M. I. van Berge Henegouwen, T. M. Moojen, T. M. van Gulik, E. A. J. Rauws, H. Obertop and D. J. Gouma
Pylorus preservation does not affect weight gain, but tumour recurrence does

927 **Different gastric emptying of solid and liquid meals after pylorus-preserving pancreatoduodenectomy**
I. Kobayashi, M. Miyachi, M. Kanai, M. Nagino, S. Kondo, J. Kamiya, M. Nakao, N. Hayakawa and Y. Nimura
Solid emptying remains delayed 6 weeks after operation

931 **Effect of growth hormone treatment on the healing of left colonic anastomoses in protein-malnourished rats**
T. Karahasanoğlu, E. Altinli, İ. Hamzaoğlu, M. Paksoy, T. Yeşildere and K. Alemdaroğlu
Improves anastomotic strength in normally nourished but not in malnourished subjects in the experimental study

Original articles (continued)

934 **Long-term results of femorotibial bypass with vein or polytetrafluoroethylene**
R. D. Sayers, S. Raptis, M. Berce and the late J. H. Miller
Evidence for the effectiveness of femorotibial bypass

939 **Provision of training in carotid surgery does not compromise patient safety**
A. R. Naylor, M. M. Thompson, K. Varty, R. D. Sayers, N. J. M. London and P. R. F. Bell
Vascular trainees' results were acceptable

943 **Thermotolerance induces heat shock protein 72 expression and protects against ischaemia–reperfusion-induced lung injury**
M. Javadpour, C. J. Kelly, G. Chen, K. Stokes, A. Leahy and D. J. Bouchier-Hayes
A possible means of reducing reperfusion injury

947 **Experimental study of the effect of adrenaline tolerance on intestinal ischaemia–reperfusion**
A. Baykal, V. Kaynaroğlu, E. Demirpençe, K. Kilinç, I. Sayek and Y. Sanaç
Evidence that catecholamines are involved in reperfusion injury

951 **Prospective analysis of quality of life in patients following infrainguinal reconstruction for chronic critical ischaemia**
I. C. Chetter, J. I. Spark, D. J. A. Scott, P. J. Kent, D. C. Berridge and R. C. Kester
Successful bypass results in early and sustained improvement in quality of life

956 **Ward *versus* intensive care management of high-risk surgical patients**
J. E. Curran and R. M. Grounds
Goal-oriented ITU care improved outcome

962 **Soave's procedure: the final sphincter-saving solution for iatrogenic rectal lesions**
J. L. Faucheron, R. Rosso, E. Tiret, E. Keli, K. P. Nugent, P. Frileux and R. Parc
Good results for a 'last stand' sphincter-saving procedure

965 **Lack of telomerase in desmoids occurring sporadically and in association with familial adenomatous polyposis**
D. K. Scates, S. K. Clark, R. K. S. Phillips and S. Venitt
Suggests the presence of alternative mechanism of tumorigenesis

970 **Identification and progression of a desmoid precursor lesion in patients with familial adenomatous polyposis**
S. K. Clark, T. G. P. Johnson Smith, D. E. Katz, R. H. Reznek and R. K. S. Phillips
Interesting proposal for a model of desmoid progression in patients with FAP

974 **Malone antegrade continence enema for faecal incontinence and constipation in adults**
K. Krogh and S. Laurberg
More data on the value of ACE in the management of constipation in adults

978 **Glutaraldehyde cross-linked collagen in the treatment of faecal incontinence**
D. Kumar, M. J. Benson and J. E. Bland
A new method to help the incontinent

980 **Functional results following the antegrade continence enema procedure**
K. R. Shankar, P. D. Losty, S. E. Kenny, J. M. Booth, R. R. Turnock, G. L. Lamont, R. J. Rintala and D. A. Lloyd
Indications for the ACE procedure are clarified

983 **Laparoscopy in the management of the impalpable undescended testis**
G. M. E. Humphrey, A. S. Najmaldin and D. F. M. Thomas
In most cases an intra-abdominal testis can be rescued laparoscopically

986 **Stimulation of inflammatory markers after blunt trauma**
P. V. Giannoudis, R. M. Smith, R. E. Banks, A. C. J. Windsor, R. A. Dickson and P. J. Guillou
A non-specific response with some pointers towards potential sepsis

991 **Sentinel node localization in patients with breast cancer**
M. M. Flett, J. J. Going, P. D. Stanton and T. G. Cooke
This method could help avoid the morbidity of axillary clearance on some patients with breast cancer

Original articles (continued)

994 **Oesophageal cancer staging using endoscopic ultrasonography**
J. Vickers and D. Alderson
An accurate technique which will provide useful staging information

999 **Influence of luminal obstruction on oesophageal cancer staging using endoscopic ultrasonography**
J. Vickers and D. Alderson
Endoscopic ultrasonography can stage tumours even in the presence of luminal obstruction

1002 **Comprehensive 1-year cost analysis of open antireflux surgery in Nordic countries**
L. Lundell, J. Dalenbäck, E. Janatuinen, J. Hattlebakk, K. Levander, P. Miettinen, H. E. Myrvold, S. A. Pedersen, K. Thor, A. Andersson, N. O. Stålhammar and the Nordic GORD Study Group
A detailed account of true costs of operation

1006 **Efficacy of anterior, posterior and total fundoplication in an experimental model**
D. I. Watson, G. Mathew, G. K. Pike, R. J. Baigrie and G. G. Jamieson
All provide early postoperative sphincter competence but what about late results?

1010 **Laparoscopy and laparoscopic ultrasonography in staging of oesophageal and cardial carcinoma**
M. G. Romijn, H. van Overhagen, E. J. Spillenaar Bilgen, J. N. M. IJzermans, H. W. Tilanus and J. S. Laméris
Looking for metastases may be rewarding in carcinoma of the cardia

1013 **Controlled trial of preperitoneal local anaesthetic for reducing pain following laparoscopic hernia repair**
G. T. Deans, M. S. Wilson and W. A. Brough
Preperitoneal local anaesthesia does not diminish port-site pain

1015 **Correspondence**

1020 **Book reviews**

1022 **Scientific Surgery**

1023 **Instructions to authors**

0007-1323(199807)85:7;1-7

Tom Benson, Teacher's Pet

The British Journal of Surgery

VOLUME 85 NUMBER 8 AUGUST 1998

Contents

Leading articles

1025 **Role of lymphadenectomy in the treatment of differentiated thyroid carcinomas**
L.-E. Tisell
Disagreement about the treatment of node metastases is particularly pronounced in the case of papillary thyroid cancer

1027 **Intra-abdominal hypertension and the abdominal compartment syndrome**
M. Schein and R. Ivatury
A plea is made for better recognition of the importance of intra-abdominal hypertension in clinical practice

Reviews

1029 **Physiological and functional outcome following ultra-low anterior resection with colon pouch–anal anastomosis**
N. Williams and F. Seow-Choen
A colon pouch produces a better result than a straight coloanal anastomosis

1036 **Quality of life after treatment for rectal cancer**
J. Camilleri-Brennan and R. J. C. Steele
Quality-of-life studies in cancer treatment are of increasing significance

1044 **Significance of angiogenesis in cancer therapy**
D. A. McNamara, J. H. Harmey, T. N. Walsh, H. P. Redmond and D. J. Bouchier-Hayes
Antiangiogenic agents offer new promise in the treatment of malignancy

Digest

1056 *Surgery Today* (*The Japanese Journal of Surgery*)
K. Sugimachi

Original articles

1058 **Central venous pressure and its effect on blood loss during liver resection**
R. McL. Jones, C. E. Moulton and K. J. Hardy
Irrespective of procedure, number of lesions or portal clamping, CVP determines blood loss

1061 **Heat shock protein 72 production in liver tissue after experimental total hepatic inflow occlusion**
C.-L. Dai, M. Kume, Y. Yamamoto, K. Yamagami, H. Yamamoto, H. Nakayama, N. Ozaki, A. M. J. Shapiro, M. Yamamoto and Y. Yamaoka
Temporary portal inflow occlusion accentuates the ischaemia–reperfusion injury in this model

1066 **Prospective randomized trial of 5- and 10-mm epigastric ports in laparoscopic cholecystectomy** (short note)
M. Golder and M. Rhodes
No objective advantage from the use of smaller ports from this randomized clinical trial

1068 **Surgical treatment of 32 patients with peripheral intrahepatic cholangiocarcinoma**
L. E. Harrison, Y. Fong, D. S. Klimstra, S. Y. Zee and L. H. Blumgart
Complete surgical excision can be safe and may cure the patient

1071 **Contribution of computed tomography to decision making in the management of adhesive small bowel obstruction**
V. Donckier, J. Closset, D. Van Gansbeke, M. Zalcman, M. Sy, J. J. Houben and J. P. Lambilliotte
Strangulation and distal obstruction can be diagnosed by CT, and require early operation

1075 **Geographical inequality in the provision of carotid endarterectomy in Scotland**
D. J. Adam, M. Bain, E. Shanks and A. W. Bradbury on behalf of the Scottish Vascular Audit Group
Patients should have equal access to vascular surgical services

What's new in *Colproctology*

12th-14th October 1998

St Mark's Hospital & Academic Institute, London

Faculty
St Mark's Hospital & Academic Institute, Imperial College School of Medicine & The Association of Coloproctology of Gt Britain & Ireland - CME Certified

Victor Fazio, *Cleveland Clinic Florida*
(Alan Parks Visiting Professor)
Volker Schumpelick, *University Clinic Aachen*
(Guest Visiting Lecturer)

An interactive and exciting opportunity for up to the minute education combined with stimulating debate. This meeting will bring together a multidisciplinary faculty of coloproctologists. The Course includes symposia, video sessions, Consultant's corner, Course Dinner.

Colonic cancer
Ulcerative colitis
Rectal prolapse
Minor anorectal conditions
Incontinence, including:
Sacral nerve stimulation
Laparoscopic colorectal surgery
Crohn's disease, Anal fistula
Stomas, Constipation
fissure, haemorrhoids, pilonidal sinus
neosphincter, artificial sphincter

To apply, write to:

MIDCENTRAL HEALTH
PALMERSTON NORTH
NEW ZEALAND

MidCentral Health is a leading and successful provider of health and disability services. Based in Palmerston North we service the Manawatu, Horowhenua and Tararua Districts.

Specialist General Surgeon

PALMERSTON NORTH HOSPITAL

We are a young enthusiastic department of five General Surgeons, looking to expand with the addition of a sixth Surgeon, whose appointment will initially be on a wholetime basis. Our workload is very broad, encompassing the full range of general surgery, with particular emphasis on breast and endocrine surgery, gastrointestinal surgery including endoscopy, minimal access and laparoscopic surgery, surgical oncology, trauma, and vascular surgery.

Palmerston North Hospital is a major hospital serving not only a base population of 150,000, but with increasing responsibility to a wider region. Some regional services cover a population of 500,000. The hospitals site redevelopment is at the advanced planning stage.

Surgical oncology is practised in conjunction and in close collaboration with the Regional Cancer Treatment Service (including medical oncology and radiation oncology) based on campus. This latter service covers the lower central North Island. We are the regions preferred provider for the developing National Breast Cancer Screening Programme. We have an excellent service from and rapport with the Emergency Department, Anaesthetic Department and ICU, pathology and laboratory services, and a full range of radiology/imaging including interventional radiology, Duplex, DSA and nuclear medicine.

The successful applicant will participate in the on-call roster for acute general surgery, as well as having and developing a subspecialty interest. Active supervision and teaching of two advanced general surgical trainees rotated from the Central Training Scheme as well as basic trainees/registrars and senior house officers is expected.

Palmerston North city is located centrally, with ready access to Wellington as well as to Lake Taupo and the ski fields. With a population of 75,000, the city has all the big city amenities - live theatre, sporting facilities, universities and polytechnic, cultural facilities including museum, science centre, library, art gallery - it has a relaxed lifestyle. For those who prefer country living, lifestyle blocks surround the city.

Applicants must be eligible for Vocational Registration with the Medical Council of New Zealand.

Closing date: OPEN

If you are interested in applying for this position,
please post or fax your curriculum vitae to the
Employee Relations Department
Palmerston North Hospital
Private Bag 11 036, Palmerston North, New Zealand

CLINICAL SURGERY

Edited by

ALFRED CUSCHIERI MD ChM FRCS, THOMAS P J HENNESSY MCh BAO FRCS FRCSI,
ROGER M GREENHALGH MA MD MChir FRCS,
PIERCE GRACE MCh FRCSI and DAVID I ROWLEY BMed Biol MD FRCS

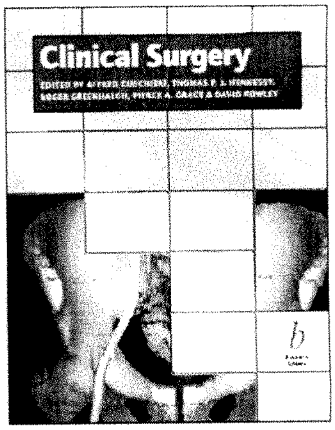
608 pages, 456 illustrations, Paperback, 0-6320-3146-8, £29.50, 1996

Clinical Surgery is a core textbook of surgery that will enable medical students and junior doctors to:

- **diagnose the disease**
- **prepare the patient for an operation**
- **deal with patient after an operation, including the management of any complications that may arise**

Clinical Surgery:

- **combines symptoms and signs** with a comprehensive overview of surgical practice
- **stresses that common things are common** by prioritising the core information that students must know
- is **ideal for revision with 52 *At a Glance* boxes** summarising the important features of the common surgical diseases on one page
- **highlights the surgical emergencies** in a section on the management of acute surgical illness and trauma
- gives a **comprehensive overview of general and specialist surgery** in which each system has a section on clinical evaluation of the patient, pathology, clinical features and management of the disease



Recent Reviews

"This book is quite simply a pleasure to own, it is lavishly illustrated in full colour, includes an extremely large amount of photographs and X-rays and 'at a glance boxes' ensuring that the reader is never bored into submission." *St. Thomas' Gazette*

"This is an attractive well laid out, textbook. Affordable, concise and most importantly readable. I feel it will not take long for it to become recognised in this field. I'm about to start my senior surgery in 2 months and I'm going to use it so it must be good!!!!" *Microscope - Nottingham University Medical School Gazette*

"In my opinion, it should be high on the list when looking for a textbook for surgery." ***Asclepiad Newspaper - The Royal London & St Bartholomews Hospital***

Cancer surgery: why some survival benefits may be artefactual

Variations in the technique, or more often the extent, of cancer operations are frequently accompanied by reports of improvement in survival rate. Such improvement may, however, be an illusion and the force at play mere artefact. Common examples of such artefacts occur in the interpretation of results from selected case series, in the use of invalid comparison, and in situations where the stage-migration phenomenon might supervene.

Horton[1] believes that case series are the weakest evidence in assessing treatment efficacy, with uncontrolled bias and confounding as potentially lethal flaws. He also notes that case series comprise nearly half the articles in a recent group of leading surgical journals. Case series (and their treacherous terrain of retrospective audit) are frequently suspect, not only because of the possibility of uncontrolled bias but also because the information may be incomplete. In the absence of the rigour of planned pro formas and prospective data collection, adverse events and deaths may be missed or censored by innocent exclusion. On the other hand, formal trial entry with prospective pro formas yields sobering morbidity and mortality rates, particularly when dedicated data handlers collect the information. The greater operative morbidity and inferior survival rates found in prospective randomized trials, compared with those of single-centre (or single-surgeon) case series and retrospective audits, attest to this.

Invalid comparisons of disparate patient groups or disease stages may yield major cancer survival differences by artefact. One example is the comparison of the present with the past: the latest cohort (who underwent the newest intervention) almost invariably have the better result when compared with the previous cohort. The greatest caution must be used in interpreting such a comparison as, from a scientific viewpoint, the populations compared are completely unstable. The new cohort may be a group of particular interest to the chief investigator, whereas the previous one was managed by various surgeons in different wards or hospitals, and in different ways. The new intervention may also exhibit a 'halo' effect, which results in better and (particularly) special care for the select group. Thus, the improved survival may not be attributed to the operation in question, but to a multiplicity of other factors.

Clinical and intraoperative selection bias, with subsequent invalid comparison, has also artefactually improved survival rates in cancer surgery. This usually occurs when easily and safely resectable cancers are treated by the *big operation*, and those posing technical problems by the *small operation*. Here, however, it is the prior probability of the disease and its stage which are the real survival determinants, and not the big or small surgery. While stage-for-stage comparisons stabilize this to some extent, within each stage pigeon-hole there is an important range of disease extent, which might be enough to allow selection bias in type of surgery. Degrees of serosal invasion or adjacent organ infiltration (within the same stage) are examples of this. The big operation can only be compared with the small operation within the controlled environment of a randomized trial, where selection bias is largely removed. The 40 years of randomized comparisons of types of surgery for breast cancer is a good example of removal of bias, with a subsequent paradigm shift in thinking about surgery for cancer at this site.

The stage migration phenomenon refers to the artefactual improvement of survival results by more extensive staging[2]. Feinstein *et al.* found that their most recent cohort of patients with lung cancer fared significantly better, in each of the tumour node metastasis (TNM) stages, than a cohort treated in the 1960s; when, however, the most recent cohort was staged as the earlier cohort had been, without the benefit of ultrasonography, computed tomography and radionuclide scanning, all differences evaporated. The improved survival results were merely an artefact of better staging. Patients in the lower stages with clinically occult disease (usually nodal) were identified, extracted and placed in more advanced stage groupings (stage migration). The lower stages were thus 'cleansed' and survival rates improved admirably. The higher stages also benefited, as they received an addition of patients with low tumour burden. Thus, while each individual prognosis remained the same, as did that of the whole group, there was an apparent improvement for each of the individual stages.

The stage migration phenomenon is a serious artefact when radical is compared with less radical surgery. Radical surgery generally produces excellent survival results in case series and in unrandomized comparisons. The radical surgery usually consists of extensive lymphadenectomy, or dissections in the mediastinum, retroperitoneum or pelvis. Extensive and accurate staging is thus achieved, the stage groupings cleansed of patients with occult disease, and outstanding survival results are obtained. A possible example of this is reflected in the contemporary debate surrounding lymphadenectomy for gastric cancer, a debate which may also expand to include the radical resection of rectal cancer.

Patients who have radical lymphadenectomy for gastric cancer may appear to have superior survival rates than those managed more conventionally. Curiously, this survival advantage is also found in node-negative cases. In the ensuing debate all agree that the differences are due to the lymphadenectomy; the question is *how* lymphadenectomy achieves this. When submitted to the test of randomized trials, however, there seems to be no significant survival advantage to lymphadenectomy; not only this, but a higher morbidity rate is found in radically treated groups[3-5]. One argument is that an artefact is at play, probably the stage migration phenomenon. The Netherlands Triallists have gone further, hypothetically comparing, first, the staging in their patients as if there were a nodal yield from only conservative (D_1) dissection and, second, as if there were a radical (D_2) nodal yield[6]. As many as 30 per cent of patients are upgraded to a higher (N_2) nodal status, as well as further migration to N_3 or N_4 status, the result being artefactual and hypothetical improvement in survival.

Most major journals, including this one, have a heightened vigilance for the above artefacts. Many editors routinely refer proferred articles for statistical review. When cancer survival rates after surgery are reported or compared in future, a great deal more detail and scientific accuracy should be required. Randomized comparison, although an incomplete paragon[7], appears to be the robust test for new variations in the surgical treatment of cancer.

Review

Endoluminal abdominal aortic aneurysm surgery

K. R. WOODBURN, J. MAY and G. H. WHITE

Department of Vascular Surgery, Royal Prince Alfred Hospital, University of Sydney, Sydney, Australia
Correspondence to: Mr K. R. Woodburn, Royal Cornwall Hospitals Trust, Treliske Hospital, Truro TR1 3LJ, UK

Background The development of devices designed for the endoluminal repair of abdominal aortic aneurysm has led to the emergence of new endovascular techniques.

Methods Articles and case reports obtained from a Medline search of the English language literature from 1989 to 1997 are reviewed. This search was carried out using the MeSH heading 'aortic aneurysm, abdominal' and the keywords 'endovascular' and 'endoluminal'.

Results Reported mortality and complication rates for endoluminal aneurysm repair are similar to those following conventional repair, with the exception of continued perfusion of the aneurysm sac which remains a major problem following endoluminal repair.

Conclusion Successful endoluminal aneurysm exclusion is associated with reduced aneurysm diameter. However, longer term results of endoluminal repair, in particular of sealed endoleaks, are required before randomized controlled trials of endoluminal *versus* conventional repair can be undertaken.

In the 46 years since the first successful replacement of an abdominal aortic aneurysm (AAA) with a homograft was reported in 1952[1], the technique of open surgical repair of AAA has been refined to the extent that the elective operative mortality rate is now about 5 per cent[2,3], while the mortality rate from ruptured AAA remains about 50 per cent[2]. These figures apply only to selected patients, however; the risks of surgical repair are greater in those with significant co-morbidity[4]. As many patients with AAA have co-existent conditions that significantly increase the risk of both elective and emergency surgery[4], less invasive endovascular techniques of repair that reduce this risk may offer a means of reducing morbidity and mortality rates following operation. This paper describes the current status of endovascular AAA repair in clinical practice. It reviews the published results of endoluminal repair in series in which outcome measures and complications have been reported.

Development of endoluminal surgery

Percutaneous treatment of occlusive arterial disease has become an increasingly accepted part of vascular surgical practice since 1969 when Dotter first reported the percutaneous placement of stainless steel coils within the arterial lumen[5]. Percutaneous angioplasty and arterial stenting are now routine. These endovascular techniques are believed to offer advantages in terms of reduced morbidity and mortality rates, reduced hospital stay, and shorter convalescence, with results that are often similar to those of surgical treatment[6].

Although initially confined to occlusive disease, endovascular techniques have now been adapted for aneurysmal disease. Animal studies indicated that it was feasible to undertake endoluminal repair of aortic aneurysms with home-made stent–graft combinations introduced using a percutaneous catheter technique[7]. The first endoluminal repair of AAA in humans was reported in 1991[8,9]. The early endoluminal devices implanted in humans were all improvised[7,8,10,11], generally using commercially available stents and graft materials[12–14]. While there are no randomized studies to support the belief that endovascular techniques offer advantages in terms of reduced morbidity and mortality rates, endovascular AAA repair is associated with less postoperative respiratory dysfunction and reduced analgesic requirements[15]. While such endoluminal repair is minimally invasive, it is not a true percutaneous technique, as it requires either iliac or femoral artery dissection and arteriotomy[10–14,16].

Since the initial report[8], the feasibility of endovascular aneurysm repair in selected patients has been clearly established and a number of commercially prepared devices are currently undergoing clinical evaluation; long-term results are still awaited. Early reports suggested that, in high-risk patients, the procedure is associated with a significant mortality rate[16]. A number of procedure-specific postoperative complications have also been identified[17–19]. As a result, a number of authors have expressed reservations about the suitability of the technique for the majority of aneurysms[20,21], and attempts are now being made to ensure that both the devices implanted and the operative procedures employed are subjected to appropriate scientific scrutiny[22–24]. At the present time, critical appraisal of the results of endoluminal AAA repair is hampered by the absence of universally adopted reporting standards[23], and by the diversity of techniques and devices used. However, in view of the potential advantages that endoluminal repair offers over conventional AAA surgery[25], it is likely that it will continue to be developed and refined.

Principles of endoluminal grafting

Endoluminal AAA repair uses minimally invasive techniques to exclude the aneurysm sac from the arterial

Paper accepted 12 January 1998

circulation by fixing a prosthetic graft within the aortic lumen. Until recently, the absence of any commercially available device resulted in the repair being performed with a wide variety of different 'home-made' devices[8–14,26–29]. Most of these consisted of some combination of tubular or bifurcated graft material fixed in position with metallic stents or other mechanism to anchor the graft material to non-dilated arterial wall above and below the aneurysm. Some of these improvised devices are now either available commercially or undergoing commercial evaluation[10,11,30]. Other devices have been developed primarily in the commercial sector[18,31].

There are three principal means of excluding an AAA from arterial blood flow (*Fig. 1*) and most devices fall into one of three design categories (*Table 1*). Within these categories there is some variation in the method of attaching the device within the aortic lumen; some favour the use of anchoring stents with unsupported graft fabric between these stents[16,30], some use a custom-designed device to attach the graft throughout its length[10], and some of the most commonly used devices consist of metallic stents covered in fabric[31,32].

Aneurysm morphology

The suitability of an aortic aneurysm for endoluminal repair depends predominantly on aneurysm morphology and device design. With current devices there is a requirement for a proximal neck of at least 15 mm of normal aorta below the renal arteries to enable proximal anchoring without the device encroaching on the renal ostia. With most reported systems the aortic neck must have a maximum diameter[33] of 26 mm, although some delivery systems may accommodate grafts suitable for use in vessels up to 30 mm in diameter[34]. In addition, the iliac vessels must be of sufficient diameter to enable the passage of the introducing device into the aorta (at least 7–9 mm in diameter). Disadvantageous morphological features are listed in *Table 2*, although increasing experience with endoluminal surgery has led to many becoming only relative contraindications. The adjunctive technical manoeuvres required to overcome some of these contraindications have been well documented[35]; in some cases devices have even been deployed with the proximal uncovered portion of the stent lying across the renal ostia, without adverse effect[13,16,30].

Initial reports suggested that between 4 and 14 per cent of patients with AAA would be suitable for endoluminal repair using an aortoaortic tube graft[19,36–38]. With the recent availability of bifurcated and aortouni-iliac devices, and increasing experience with endoluminal techniques, some authors now report that up to 50 per cent of AAAs may be suitable for endoluminal repair[33,38,39]. These figures need to be interpreted with caution, however, as there remains considerable debate about the need to operate on small aneurysms[20,40], particularly in the absence of any reliable data on aneurysm expansion rates[41]. Furthermore, endoluminal surgery is currently being carried out in tertiary referral centres with highly selected patient populations; this is hardly representative of the generality of aneurysm management.

Radiological imaging and endoluminal surgery

In contrast to open repair, where the vascular surgeon can adapt both graft and anastomoses to the aneurysm morphology[20], endoluminal repair requires that the graft device is of the correct diameter, length and configuration at the time of deployment. Precise preoperative measurements are therefore needed[38,42]. These are best obtained by biplanar angiography with a calibrated catheter to correct parallax and magnification errors[42,43].

Fig. 1 Diagrammatic representation of the three main categories of endoluminal repair of abdominal aortic aneurysm. a Aortoaortic tube graft; b aortobi-iliac graft; c aortouni-iliac graft with occlusion of contralateral iliac artery and femorofemoral crossover graft

Table 1 Three main categories of device currently being implanted for endoluminal repair of abdominal aortic aneurysm

Device type	Subgroups	Availability
Aortoaortic	Graft with proximal and distal stent or other attachment device	EVT (Endovascular Technologies, Menlo Park, California, USA) Parodi device*
	Externally covered stent	Passager (Boston Scientific, Oakland, New Jersey, USA)
	Internally covered stent	Corvita[32] (Corvita, Miami, Florida, USA)
	Modular graft with attachment device along graft length	Sydney endograft (Baxter Healthcare, Irvine, California, USA)
Bifurcated aortoiliac graft	Graft with proximal and distal stent or other attachment device	EVT Chuter–Gianturco*
	Externally covered modular stents	Vanguard (Boston Scientific) Talent (World Medical, Florida, USA) Perth bifurcated system*
	Internally covered stents	Corvita
	Modular graft with attachment device along graft length	Sydney endograft
Aortouni-iliac graft (and femorofemoral crossover)	Graft with proximal and distal stent or other attachment device	EVT Ivancev–Malmo system* Parodi device* Leicester device*
	Modular graft with attachment device along graft length	Sydney endograft

*Not currently available as commercially produced devices. All other devices are either undergoing clinical evaluation or are commercially available in some countries

Angiography in the assessment of AAA for endoluminal repair has limitations[43,44] and additional imaging is required[23]. Most centres use contrast-enhanced computed tomography (CT)[30,34,45], preferably with spiral acquisition and three-dimensional reconstruction[18,39,46]. Some authors advocate undertaking CT as the initial imaging procedure to determine suitability for endoluminal repair before angiography[18,34]. Future developments in preoperative imaging are likely to include the application of magnetic resonance imaging techniques[30,46–48].

Intraoperative monitoring and assessment of graft deployment are currently carried out using fluoroscopy[42,49], although some authors advocate the additional use of intravascular ultrasonography to determine graft length and site of deployment[42,50]. At present there are significant limitations to the routine use of intravascular ultrasonography[51], although it may have a role where mural thrombus or vessel wall irregularity is present at the site of graft anchoring. In these conditions angiography alone cannot confirm that the endoluminal device is accurately anchored to the aortic wall, rather than embedded in intraluminal thrombus, and interrogation of proximal and distal ends of the graft using intravascular ultrasonography can confirm appropriate apposition between the anchoring device and the vessel wall[41,51].

Table 2 Morphological features that do not favour endoluminal repair of abdominal aortic aneurysm

Involvement of renal artery origins*
Infrarenal proximal aortic neck length < 15 mm*
Proximal aortic diameter > 26 mm*
Common iliac artery diameter < 9 mm*
Common iliac artery < 25 mm long
Common and external iliac diameter > 14 mm
Distal aortic cuff < 10 mm (for aortoaortic tube grafts)
Thrombus within lumen at aortic neck
Angulation of iliac arteries > 90°
Angulation of proximal aortic neck > 60°

*Absolute contraindications with currently available devices; other features are relative contraindications

Mortality rate following endoluminal aortic aneurysm repair

Most of the published results indicate that the perioperative mortality rate following endoluminal AAA repair is similar to that reported for open repair (*Table 3*). The experimental nature of the technique has meant that many of the early devices were implanted in high-risk groups of patients who had often been refused the conventional operation[16,28,55,57]. While the reasons for this refusal are not always documented, 32 per cent of patients undergoing endoluminal repair in one large series were classed as American Society of Anesthesiologists grade IV[39]. In some series a small number of devices were inserted on an emergency basis for leaking aneurysms or contained ruptures[28,45,57]. When these factors are considered, in conjunction with the 'home-made' nature of the initial devices and the fact that the reported results include the initial 'learning curve' cases, it seems reassuring that the mortality rate associated with endoluminal repair is similar to that of conventional surgery.

Results of endoluminal aneurysm surgery

The technical success rate for endoluminal repair, defined as proper placement of the graft using endoluminal techniques without perigraft endoleakage, death or graft occlusion within 30 days of implantation[23], ranges from 48 to 95 per cent depending on the device deployed (*Table 3*). This is much lower than the success rate of conventional surgery which is in excess of 93 per cent[3]. Many endoluminal procedures require the placement of additional stents and devices to complete the exclusion of the aneurysm sac and to correct leaks noted at the time of initial device deployment[19]. These cases are not classed as primary technical successes[23]. Small leaks often seal spontaneously[39,53,57]. Correction of major leaks is usually attempted at the time of initial surgery or in the early postoperative period[19,39,55], in the same way that a vascular surgeon will insert additional sutures at an anastomosis to correct leaks observed when the clamps are removed during an open AAA repair. If these cases that are salvaged successfully with an additional endoluminal method are included, the success rate for the procedure reaches 100 per cent for some graft configurations (*Table 3*).

The mean hospital stay following successful endoluminal repair ranges from 3 to 12 days[39,42,45], with up to 72 per cent of patients discharged within 3 days of surgery in one series[53]. A number of authors have noted that with increasing experience they have been able to reduce the length of stay by 50 per cent[39,45].

The mean duration of operation reported for endoluminal procedures is 88–193 min, with an overall range of 25–480 min[28,39,42,45,53]. Some currently available devices are associated with a significant incidence of device-related problems that adversely affect the operating time, although not affecting outcome measures[58]. With more experience of endoluminal techniques, and improved devices and delivery systems, it is likely that these problems will be overcome. Operating times should, therefore, decrease and few patients will be subjected to prolonged endoluminal procedures[20].

Current reports of endoluminal AAA repair suggest that many of the aneurysms treated met recognized criteria for open surgical intervention[20]. All series report mean diameters between 51 and 60 mm, with AAAs as small as 36 mm and as large as 97 mm undergoing successful endoluminal surgery[39,54]. It is probable that smaller aneurysms are morphologically more suited to endoluminal repair[42] and the relevance of treating aneurysms of this size is debatable[20,40]; the favourable results associated with endoluminal repair may reflect a selection bias towards smaller lesions.

Table 3 Reported results of endoluminal repair of abdominal aortic aneurysm

Reference	Year	Device	*n*	Primary technical success	Success after additional endoluminal procedure	Conversion to open repair	Persisting endoleak or other late failure	Other postoperative complications	30-day mortality

Values in parentheses are percentages. Primary success refers to primary technical success rate as defined in the SVS/ISCVS (Society for Vascular Surgery/International Society for Cardiovascular Surgery) reporting standards[23]. *Totals include cases in which spontaneous thrombosis of endoleaks occurred (number in square brackets) within 6 months of surgery (primary clinical success[23]). †Includes one failed deployment treated by axillofemoral grafting. n.a., Data not available; GAD, graft attachment device

Early complications

The high complication rate following endoluminal repair includes complications that are exclusive to endoluminal surgery. There appears to be a specific 'postimplantation syndrome'[39] which takes the form of a spontaneously resolving pyrexia of unknown origin; it is of variable incidence and has not been reported by all authors (*Table 4*). The obligatory use of large-diameter delivery systems often results in injury to common femoral or iliac arteries, while the groin wound complication rate reflects the requirement for surgical exposure of these vessels (*Table 4*). Renal impairment following endoluminal repair may be secondary to the administration of large quantities of intravenous contrast agent[56]. Complications that are common to both endoluminal and conventional repair seem to occur with a similar incidence regardless of method[59,60].

Embolic events have been reported after endoluminal repair and in two centres these were fatal[14,42]. While this is a cause for concern, the overall incidence of peripheral embolic events following endoluminal surgery is less than that described for conventional repair[59].

Endoleaks

Endoleak is defined as the persistence of blood flow outside the graft lumen but within the aneurysm sac or adjacent vessels in which the graft is deployed[19,61]. It is a complication exclusive to endoluminal aneurysm repair. Endoleak that occurs at initial deployment may be due to a number of factors[62] and often arises at the site of proximal or distal fixation of the device. In selected cases further endovascular intervention to repair such primary endoleakage may be successful[19,39,42,62]. Trauma to the device fabric at the time of implantation has also resulted in both early and late endoleak[39,63]. Some early postoperative endoleakage appears to seal spontaneously (*Table 3*), although the long-term outcome of such sealed endoleaks is unknown[62] and they have been reported to recur[19]. Endoleakage can occasionally be identified using colour duplex ultrasonography to identify flow within the sac[19], but contrast-enhanced CT is the favoured method of follow-up[63] (*Fig. 2*) and has become the imaging modality of choice. If an endoleak is suspected, further investigation should be carried out using angiography.

Late complications

Although long-term follow-up of endoluminal AAA repair is not available, some late complications have already been observed. A small number of graft limb thromboses occurred early in the clinical development of a few bifurcated devices, but these have now been modified in an attempt to prevent further problems[13,30]. While these particular cases were related to early technical problems, late graft limb thrombosis may occur with endoluminal devices in the same way that it may occur in conventionally placed grafts[3]. Graft infection has also

Values in parentheses are percentages. Only series in which individual complications are specified have been included. Complications are categorized according to the SVS/ISCVS (Society for Vascular Surgery/International Society for Cardiovascular Surgery) reporting standards for infrarenal aortic aneurysm repair[23] been reported as a late complication of endoluminal surgery[14,30], although the only bacteriologically confirmed case of infection arose in the femorofemoral crossover component of an aortouni-iliac graft[14]; there have so far been no confirmed reports of infected endoluminal devices themselves. Most late complications can be attributed to the development of endoleaks (*Table 5*). Persisting collateral flow into the excluded aneurysm sac from patent lumbar or inferior mesenteric vessels may result in late endoleak[39,63], although this appears to be a rare complication[19] and it is not routine practice to occlude these vessels before endoluminal repair of AAA. Some authors believe that the presence of intraluminal thrombus protects against endoleakage, but this remains to be confirmed.

Late endoleaks more commonly occur as a consequence of failure of the proximal or distal attachment device to remain in close apposition to the vessel wall[62,63]. This may reflect inappropriate patient selection, with the deployment of endoluminal devices in less than ideal aneurysm morphology, or malpositioning of the device early in the learning curve of endoluminal operating experience[30]. In some instances component failure and subsequent graft migration may contribute[53]. Many of these endoleaks can be treated by additional endovascular procedures[19,64,65]. The long-term results of treating late endoleaks are not available.

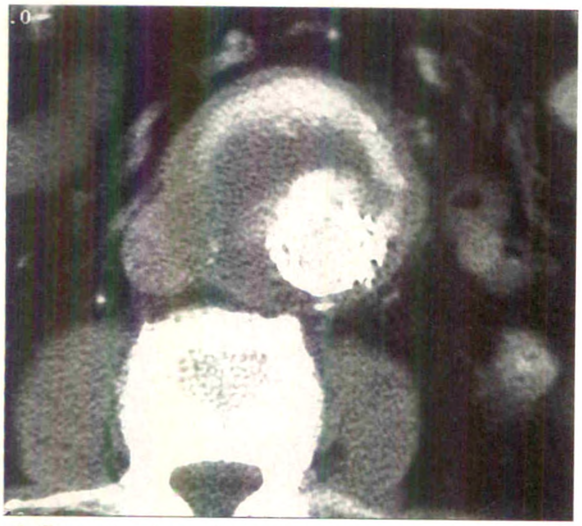

Fig. 2 Contrast-enhanced computed tomogram following endoluminal repair of abdominal aortic aneurysm. The presence of an endoleak is confirmed by the pool of white contrast agent within the excluded aneurysm sac

Effect of endoluminal grafting

In addition to a reduced postoperative hospital stay following endoluminal AAA repair, a number of authors have reported that successful AAA exclusion is accompanied by a reduction in the diameter of the aneurysm sac on follow-up CT[39,63,66,67]. This reduction in diameter is not seen in cases of endoleak or collateral perfusion[63,67] and may prove to be a useful indicator of these complications during routine follow-up. Paradoxically, it has also been noted that the reduced AAA diameter is accompanied by a dilatation of the proximal aortic neck at the site of proximal device fixation[62,66]. If this dilatation is progressive, it may result ultimately in device migration at the proximal neck, with subsequent endoleakage and failure to maintain aneurysm exclusion. Further long-term follow-up studies will clarify this issue.

The future

The encouraging results of the early studies should ensure the continued development and improvement of endoluminal devices. Endovascular AAA repair is unlikely to become exclusively percutaneous if it is to be applied to as broad a spectrum of aneurysm morphology as possible and if the risks of embolic complications are to be minimized. However, it is likely that improved device design will enable a significant number of procedures to be performed percutaneously.

The requirement for precise preoperative imaging in endoluminal AAA repair makes the technique of little value (with currently available devices) in the acute situation of rupture, where one might expect the benefits of the technique to be the greatest[20]. Nevertheless, it may be appropriate to treat a leaking aneurysm in the haemodynamically stable patient by endoluminal methods. The technique may also have a role in the treatment of thoracic aortic aneurysm[45], where the benefits of endoluminal surgery may be even more marked than in the abdominal setting. The success of endoluminal surgery depends on appropriate patient selection. Undertaking endoluminal surgery in patients with inappropriate aneurysm morphology will increase both the primary failure rate and the incidence of late endoleaks. It may

Table 5 Causes of late failure reported following endoluminal repair of abdominal aortic aneurysm

					Endoleak				
Reference	Year	Total no. of late failures	Graft thrombosis	Graft infection	Fixation site failure	Device migration	Fabric failure	Lumbar or mesenteric backbleed	Further endoluminal treatment successful

White *et al.*[45]	1997	6	0	0	6	0	0	0	2

Endoleak refers to clinical failure of endoluminal surgery because of leaks persisting or arising *de novo* more than 6 months after graft implantation[23] not prove possible to increase the proportion of patients suitable for endoluminal AAA repair above the 30–50 per cent currently quoted[33,38,39]. While this figure can be increased by treating smaller aneurysms whose morphology is more suited to successful endoluminal repair[42,68], there is no justification for this approach until the results of endoluminal surgery are improved significantly.

Data regarding the suitability of an AAA for endoluminal surgery are currently based on the experience of tertiary referral centres with considerable referral bias. Having demonstrated that endoluminal AAA repair is feasible in selected patients who would previously have undergone open repair, it is important to determine the percentage of aneurysms currently undergoing open surgical repair that would be suitable for endoluminal repair. This has not been done outwith the aforementioned highly selected patient populations, and a determination of how widely applicable this new technique will be, based on currently accepted indications for AAA repair, is required to allocate resources properly.

Considerable concern remains about the long-term outcome of endoluminal surgery. The durability of devices currently undergoing evaluation is unknown and component failure has already led to design revision[53]. Increased length of follow-up will probably reveal design weaknesses in other devices, and many revisions and modifications will be required before the ideal endoluminal device is developed.

Persisting or late-onset endoleak is associated with continued aneurysm expansion[60] and fatal rupture[30], and the outcome of treated and untreated endoleaks will be a major factor in determining the future of endoluminal repair. A recent comparison between endoluminal and open AAA repair in one centre has indicated that, although postoperative survival is similar between patient groups, survival with a successful outcome (continuing graft function without endoleak) is significantly higher following open AAA repair[69]. It therefore remains imperative that long-term follow-up data are available from a number of centres before undertaking randomized controlled trials of endoluminal AAA surgery *versus* conventional repair.

Background Injury activates a cascade of local and systemic immune responses.

Methods A literature review was undertaken of lymphocyte function in wound healing and following injury.

Results Lymphocytes are not required for the initiation of wound healing, but an intact cellular immune response is essential for a normal outcome of tissue repair. Injury affects lymphocyte immune mechanisms leading to generalized immunosuppression which, in turn, increases host susceptibility to infection and sepsis. Although the exact origin of post-traumatic immunosuppression remains unknown, stress hormones and immunosuppressive factors, such as inflammatory cytokines, prostaglandin E_2 and nitric oxide, affect lymphocyte function adversely. Post-traumatic impairment of T lymphocyte immune function is reflected in decreased lymphocyte numbers, as well as altered T cell phenotype and activity. Antibody-producing B lymphocytes are variably affected by injury, probably secondary to alterations of T lymphocyte function, as a result of their close interaction with helper T cells. Therapeutic modulation of the host immune response may include non-specific and specific interventions to improve overall defence mechanisms.

Conclusion Early resuscitation to restore lymphocyte function after injury is important for tissue repair and the prevention of immunosuppression.

Injury elicits local repair mechanisms and a systemic defence response in which cytokines and other metabolic products of activated lymphocytes can act either beneficially to provide enhanced host resistance or deleteriously to depress the function of remote organs and cause systemic inflammation. After minor injury the systemic host response may be negligible; severe trauma, however, is associated with altered metabolism characterized by catabolism and wasting of lean body mass, and a compromised immune system. Delayed death after trauma, occurring days to weeks after injury, is attributed to abnormalities of the immune system, leading to infection.

Non-specific host defence mechanisms include polymorphonuclear and mononuclear phagocytes, natural killer (NK) cells and products of complement activation. Specific defence mechanisms include antibody formation by B lymphocytes, direct microbial killing by T lymphocytes and T lymphocyte activation of mononuclear phagocytes. Changes in leucocyte numbers and function may reflect both the cause and the effect of infection, sepsis and injury. What follows is a review of the immune response to injury in general, followed by a discussion of lymphocyte function in wound healing and after injury.

Non-specific defence

Immune response following injury affects innate and adaptive immunity. The innate or non-specific antigenic features include intact physical barriers of skin and mucous membranes, the alternate pathway of complement activation which is spontaneously active in plasma and can opsonize or destroy bacteria while sparing host cells, and immune-competent cells and their soluble mediators. Cellular elements include macrophages, neutrophils, NK cells and endothelial cells. Antigenic products from pathogenic organisms or arising from tissue destruction activate defence mechanisms. Activated cells of the innate immune system in turn synthesize potentially toxic mediators, including cytokines, such as tumour necrosis factor (TNF) α, interleukin (IL) 1 and IL-6, as well as kinins, platelet activation factor, eicosanoids and radicals (e.g. hydrogen peroxide and nitric oxide). Normal cellular and humoral immune function is necessary to restore host integrity; overwhelming inflammatory response, however, leads to immune dysfunction and increases susceptibility to infection and sepsis.

Complement activation

The initiating factors are many but the subsequent inflammatory responses are qualitatively similar. Damaged tissue, foreign material or bacterial lipopolysaccharide can activate the alternate complement pathway. Complement activation results in assembly of C5b–9 (membrane attack complex) on the surface of Gram-negative bacteria with lysis of the bacteria after successful attachment. Products of the activated complement system, such as C3a and C5a, increase capillary permeability and play an important role in the initiation of the chemotaxis process[1,2]. Following burn injury, altered concentrations of complement components and altered leucocyte function have been reported[3,4]. Clinically, increased levels of C3a and membrane attack complex have been found to be associated with the development of multiple organ dysfunction following trauma[5].

Paper accepted 25 November 1997

Phagocytic cells

Fixed phagocytic cells, such as dendritic cells and macrophages, are the first line of cellular defence. Phagocytosis and intracellular killing are the hallmark of the non-specific immune response. To facilitate antigen engulfment, opsonization of foreign protein must occur, a process in which foreign particles are coated with plasma cell-derived immunoglobulin and/or activated components of the complement system. The coated antigen is then bound to the Fc or complement receptors on the phagocytic cell, facilitating uptake. In addition to Fc and complement receptors, macrophages have on their surface receptors that recognize various microbial constituents, including the macrophage mannose receptor, CD14, a molecule that binds bacterial lipopolysaccharide, and the leucocyte integrin CD11b–CD18, also known as Mac-1[6,7]. The second important effect of the interaction of macrophages with pathogens is the secretion of cytokines; this is induced by bacteria binding to macrophage receptors. Important macrophage-derived cytokines (monokines) which occur in response to bacterial products include IL-1, IL-6, IL-8, IL-12 and TNF-α. The combined local effect of these mediators contributes to the local reaction to injury in the form of an inflammatory response. Systemically, these inflammatory monokines initiate an acute phase response, leading to the release of acute phase proteins from the liver, neutrophil mobilization from the bone marrow, protein mobilization from muscle and other effects.

Impaired function of the phagocytic cell system after injury was demonstrated more than 20 years ago[8,9]. Altered monocyte function is reflected in the altered release of soluble mediators[10]. Also, with respect to adaptive immunity, macrophages are antigen-presenting cells that are crucial for the activation of antigen-specific T cells. Macrophages efficiently ingest pathogens and are induced by infectious agents to express major histocompatibility complex (MHC) class II molecules and costimulatory activity. Following both experimental and clinical injury, antigen presentation and MHC class II molecule expression have been shown to be depressed, leading to impaired immune response[11].

Polymorphonuclear leucocytes

Circulating polymorphonuclear leucocytes are recruited at the site of inflammation by soluble mediators, causing cell adherence, transcapillary migration and chemotaxis. CD11b–CD18 is the ligand for the endothelial cell-expressed intercellular adhesion molecule 1, and this interaction causes the tight adhesion that is necessary for transmigration of neutrophils into the surrounding tissue[12,13]. Clinically, increased neutrophil CD11b expression has been demonstrated after major trauma and in patients with sepsis[14,15]. In severe illness endothelial cell activation is not confined to the original site of injury. In patients with peritonitis and multiple organ dysfunction syndrome (MODS), extensive expression of endothelial leucocyte adhesion molecule 1 occurs in endothelium remote from the abdomen and in the absence of bacteria in the areas examined[16]. Sequestration of neutrophils and leucostasis have been demonstrated both during hypovolaemic shock and after reperfusion[17,18]. Activated neutrophils release inflammatory mediators, such as oxygen radicals and proteases, leading to endothelial cell swelling and organ damage. After severe injury neutrophil function may be compromised, contributing to postinjury immunosuppression[19–21].

Natural killer cells

NK cells, non-T, non-B lymphoid cells bearing no known antigen-specific receptors, play an important part in innate immunity. The exact mechanism by which these cells distinguish between infected and uninfected host cells is not completely clear. It appears, however, that cytokine-activated NK cells selectively kill target cells bearing low levels of MHC class I molecules[22]. Also, infected cells bound by antibodies may be destroyed by NK cells, a phenomenon known as antibody-dependent cell-mediated cytotoxicity (ADCC). ADCC seems to be mediated by the FcγRII receptor (CD16) on NK cells[23]. Suppressed NK cell activity has been reported following both experimental and clinical injury[24–26], suggesting that impaired NK cell function may contribute to increased susceptibility to post-traumatic infection. Non-adaptive immune mechanisms play an important role both on their own, in controlling infection in its early phase while the adaptive lymphocyte-mediated immune response is being developed, and also through their impact on the adaptive immune response.

Role of lymphocytes in wound healing

Tissue injury initiates a cycle of inflammation, cellular migration and replication, and connective tissue deposition and remodelling, to restore tissue integrity. It is clear that T cells play a modulatory role in wound healing, although the full range of their effects is incompletely understood. There is no evidence that B lymphocytes play a significant role in wound healing[27]. Histologically, significant numbers of T lymphocytes appear in rat wounds around the fifth day after wounding, peaking around day 7[28,29].

T cell function in wound healing

Direct evidence for lymphocyte involvement in the control of wound healing is provided by studies examining the effects of *in vivo* lymphocyte depletion. Global T cell depletion, using the 3OH12 monoclonal antibody against the Thy 1.2 antigen, causes a marked reduction in mechanical strength and collagen content of a wound[30]. Anti-Lyt2 antibody-induced depletion of the CD8$^+$ subset causes marked enhancement of wound healing[31]. These findings suggest a possible role for CD8$^+$ cells in the overall downregulation of wound healing activity. It might be expected that CD4$^+$ T helper cells would promote such activity. Depletion of this subset by an anti-L3T4 antibody, however, has no effect on either mechanical strength or collagen formation[31]. Therefore, an incompletely characterized lymphocyte population bearing the all-T cell antigenic marker Thy 1.2, but not the mentioned determinant for CD4 or CD8, seems to be responsible for the promotion of wound healing, as its depletion impairs wound healing (*Fig. 1*).

Support for these findings is provided by experiments in congenitally athymic nude mice[32]. These animals have a profoundly impaired T cell-dependent system and display significantly enhanced wound breaking strength and collagen deposition in response to injury, compared with normal thymus-bearing animals. T cell reconstitution of

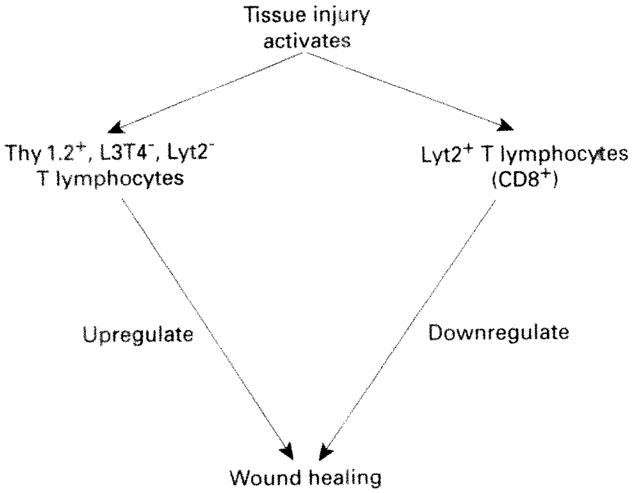

Fig. 1 Proposed role of T lymphocytes in wound healing. A T cell population (Thy 1.2$^+$, L3T4$^-$, Lyt2$^-$ seems to promote wound healing. Lyt2$^+$ T cells (CD8$^+$) appear to downregulate wound healing, as their depletion enhances wound mechanical strength and collagen formation

nude mice with syngenic splenic T lymphocytes results in a significant decrease in mechanical strength and collagen formation, to values similar to those observed in normal euthymic controls. This supports the hypothesis that a subset of T cells normally plays a downregulatory role in wound healing.

Some information regarding the role of T lymphocytes in wound repair has been obtained from *in vivo* studies which used lymphotrophic or lympholytic agents[33]. The parenteral or enteral administration of agents known to enhance thymic and T lymphocyte function, such as growth hormone[34], vitamin A[35] or arginine[36], leads to an increase in mechanical strength and collagen deposition. Agents that suppress T lymphocyte function, such as steroids and retinoic acid, markedly impair wound healing[35]. In addition, systemic treatment with cyclosporin and tacrolimus (FK506), both immunosuppressive drugs known to inhibit T cell proliferation and IL-2 synthesis by interfering with intracellular calcineurin, leads to impaired wound healing in rats[37,38]. Wound nitric oxide synthesis, which has been shown before to be critical for normal healing[39], is decreased by treatment with tacrolimus. Thus, impaired healing by tacrolimus may be a reflection of diminished wound nitric oxide synthesis.

Modification of T lymphocyte function by adult thymectomy, which prevents the induction of CD8$^+$ T cells, causes an increase in the mechanical strength of wounds[40]. This effect can be reversed by intraperitoneal placement of autologous thymic grafts in thymectomized rats. Conversely, administration of thymic hormones, such as thymulin or thymopentin, results in impaired wound healing as assessed by mechanical strength and collagen deposition[33]. These data suggest that the thymus has an inhibitory effect on healing.

Role of lymphokines in wound healing

The T cell contribution to the healing process is mediated, in part by the release of soluble factors (lymphokines) (*Table 1*). A variety of *in vitro* and *in vivo* studies has tried to elucidate the role of lymphokines in fibroblast regulation and in *in vivo* tissue repair.

In vitro *studies.* Many lymphokines are capable of modulating fibroblast replication, migration or collagen synthesis *in vitro*. Some, such as transforming growth factor (TGF) β or interferon (IFN) γ, are well characterized, whereas many other mediators that can modulate *in vitro* fibroblast activity remain incompletely characterized. Both inhibitory and stimulatory lymphokines for all aspects of fibroblast function have been described. While the *in vivo* regulation of wound healing probably consists of a complex multifactorial interaction between various cytokines and growth factors, including the T cell-derived lymphokines, it remains unclear how these factors act in temporal sequence and in concert.

In vitro, TGF-β is a potent fibroblast chemotactic molecule which stimulates collagen and fibronectin synthesis, and enhances collagen–matrix contraction by fibroblasts[41,42]. TGF-β, however, does not have a significant growth enhancing effect on fibroblasts. In doses greater than 100 ng/ml it appears to inhibit fibroblast growth[43]. This suggests that the major role of TGF-β is to halt proliferation and stimulate important effector functions of the fibroblast, such as collagen synthesis. TGF-β also induces monocyte chemotaxis and secretion of fibroblast growth factors, including IL-1.

Fibroblast activating factor (FAF), which stimulates fibroblast proliferation, has been described in humans and guinea-pigs, and is produced by activated lymphocytes[44]. IFN-γ, on the other hand, is a potent inhibitor of fibroblast proliferation and collagen synthesis[45]. TNF-α, released by macrophages and activated lymphocytes, induces the proliferation of growth-arrested fibroblasts in a dose-dependent manner (10–500 ng/ml)[43]. In doses greater than 500 ng/ml there is an apparent suppression of fibroblast growth by TNF-α as a result of cell death. In the presence of high concentrations of TNF-α and indomethacin, an inhibitor of prostaglandin (PG) E_2 synthesis, the cells remain viable but no longer proliferative. This suggests that in high doses TNF-α-induced fibroblast cytotoxicity is in some way prostanoid mediated. TNF-α has been shown to inhibit collagen and fibronectin synthesis by fibroblasts, and to diminish endothelial cell proliferation[46].

It is evident that lymphokines can exert both stimulatory and inhibitory signals on all aspects of fibroblast activity, and there seems to be a balance between these effects. While knowledge of how this balance is achieved is scant, it is clear that an imbalance may result in wound failure or, conversely, in excessive fibrosis. It has been demonstrated that the continued presence of antigenic stimulus at a healing site leads to excessive fibrosis, presumably due to continued activation of T lymphocytes with unchecked production of FAF[47].

In vivo *studies.* The presence of a number of lymphokines has been confirmed at the wound site *in vivo*. In a murine model, the presence of biologically active IL-1, TNF-α and IL-6 has been demonstrated, while IL-2, IL-3 and IL-4 could not be detected[48]. In addition, TGF-β occurs in significant quantities although biological activity is uncertain[49].

Another approach to the assessment of the role of lymphokines in wound healing is to administer recombinant factors *in vivo*, either locally or systemically, and to examine the response of wounds. Application of TGF-β to linear incisions in rats leads to increased mechanical strength and collagen deposition, with a concomitant rise in mononuclear cell and fibroblast infiltration[50,51]. It appears that the concentrations and ratios of the different TGF-β subtypes 1, 2 and 3, and their corresponding receptors at the wound site, seem greatly to influence the effect of this lymphokine on collagen quality and quantity. Interestingly, the exogenous addition of neutralizing antibody to TGF-$\beta_{1,2}$ reduces scar formation after cutaneous injury in rats[52]. Early application of this neutralizing antibody to an incisional wound reduces the degree of macrophage infiltration at the wound site, neovascularization, and the amount of fibronectin and collagen, without reducing the tensile strength of the wound. It also improves the architecture of the neodermis to resemble that of the normal dermis and thereby reduces scarring.

Systemic administration of human recombinant IL-2 to rats increases the mechanical strength of wounds with an associated rise in collagen deposition[53]. Wound fluid, on the other hand, contains an IL-2 inhibitory factor which has been postulated as playing a role in the down-regulation of the exuberant cell proliferation and activity that characterizes the early phases of wound healing[54].

The administration of IFN-γ via subcutaneously implanted osmotic pumps in mice results in a decrease in the thickness and collagen content of the capsule that forms around the pumps[55]. The *in vivo* abrogation of endogenous TNF-α by topical application of anti-TNF-α polyclonal antiserum results in a significant increase in collagen deposition[56]. Also, in a different study, when TNF-α was applied topically, decreased mechanical strength of incisional wounds in rats was noted[57]. Hypertrophic scars on the other hand have been demonstrated to contain fewer TNF-α-producing cells[58], suggesting that physiological TNF levels may play an important role in the downregulation of excessive collagen production in wounds.

Clinical trials investigating the effect of cytokines and growth factors on healing have focused mainly on chronic wounds. Since 1986, when it was first demonstrated that locally acting growth factors may promote healing of chronic cutaneous ulcers in patients[59], numerous clinical studies have been conducted using either autologous platelet-derived or recombinant growth factors. Improved healing has been reported by several authors[60–62], whereas others have found no beneficial effects from the topical treatment of chronic wounds with growth factors[63–65]. Several multicentre trials are now under way to confirm or refute these findings from small studies. Part of the

Table 1 Effects of lymphokines on immune and wound cells

Lymphokine	Abbreviation	Cellular effects
Interleukin 1	IL-1	Stimulates leucocyte chemotaxis, keratinocyte migration, fibroblast proliferation
Interleukin 2	IL-2	Stimulates T cell growth, promotes T helper cell activity, augments cytotoxicity, stimulates B cell differentiation
Interleukin 3	IL-3	Stimulates both T and B cell maturation and mast cell growth; multipotential haemopoietic cell growth factor
Interleukin 4	IL-4	Stimulates T and B cell and mast cell growth, B cell antibody production, inhibits macrophage activation
Interleukin 5	IL-5	Stimulates B cell growth and antibody production, enhances eosinophil differentiation
Interleukin 6	IL-6	Stimulates T and B cell activity, inhibits fibroblast proliferation
Interleukin 8	IL-8	Stimulates leucocyte chemotaxis and activity
Interleukin 10	IL-10	Inhibits cytokine release by type 1 T helper lymphocytes and macrophages
Interferon γ	IFN-γ	Stimulates macrophage activity and B cell differentiation, stimulates and inhibits fibroblast proliferation, inhibits collagen production and collagen cross-linking, inhibits endothelial cell proliferation, increases endothelial cell adhesivity for lymphocytes
Tumor necrosis factor α	TNF-α	Stimulates neutrophil and macrophage activity, inhibits collagen synthesis by fibroblasts, inhibits endothelial cell proliferation, stimulates fibroblast proliferation
Lymphotoxin (tumour necrosis factor β)	LT (TNF-β)	Inhibits B cell growth, stimulates fibroblast proliferation and collagen synthesis
Transforming growth factor β	TGF-β	Inhibits B cell growth, T cell and macrophage activation, activates neutrophils, stimulates fibroblast migration, stimulates and inhibits fibroblast proliferation, stimulates fibroblast collagen synthesis, inhibits endothelial cell proliferation
Granulocyte–macrophage colony-stimulating factor	GM-CSF	Stimulates B cell differentiation, inhibits T cell growth, stimulates growth of mixed colonies of granulocytes and macrophages from bone marrow progenitor cells
Fibroblast inhibition factor	FIF	Inhibits fibroblast migration
Fibroblast inhibitory factor	IF	Inhibits fibroblast proliferation
Fibroblast activating factor	FAF	Stimulates fibroblast proliferation and collagen synthesis
Macrophage chemotactic factor	MCF	Stimulates macrophage migration
Macrophage inhibitory factor	MIF	Inhibits macrophage activity
Macrophage activating factor	MAF	Stimulates macrophage activity

explanation for the conflicting results so far may be the lack of appreciation of the complex pathophysiology of non-healing wounds, the heterogeneous groups of patients used and pharmaceutical considerations[66].

Thus T lymphocytes and their soluble mediators have been demonstrated, both *in vitro* and *in vivo*, to possess the capacity to modify essential steps in the process of wound healing. Defined subsets of T cells express stimulatory or inhibitory effects on repair mechanisms and take part in a balanced system of wound cell regulation. An intact cellular immune response appears to be critical for the successful outcome of healing.

Immunosuppression after injury

The immune response after injury involves the release and interplay of numerous soluble mediators (*Fig. 2*), which may act in an endocrine, paracrine or autocrine fashion. Also, their cellular sources are diverse, including hormone glandular cells, immune-competent inflammatory cells and mesenchymal cells.

Stress hormones

Following injury several endogenous hormones are released into the systemic circulation, including catecholamines and glucocorticoids. This neuroendocrine response adversely affects both the humoral and cellular immune systems. Catecholamines impair T cell proliferation, IL-2 receptor expression and immunoglobulin production by B lymphocytes[67–69].

Glucocorticoids are known to impair the phagocytic activity of polymorphonuclear leucocytes[70], and to decrease T cell blastogenesis and IL-2 production, leading to impaired cellular immunity[71]. They also affect macrophage function, leading to decreased expression of the Ia antigen (murine MHC class II equivalent) and IL-1 synthesis[72]. Bilateral adrenalectomy abolishes the fall of both T and B lymphocyte numbers in the circulation after injury, indicating that stress hormones play a significant role in these changes[73].

Fig. 2 Systemic effect of trauma on T cell-mediated immunity IL, interleukin; IFN, interferon; TNF, tumour necrosis factor

Immunosuppressive factors

Trauma is associated with impaired response to delayed-type hypersensitivity skin tests[74], decreased rate of allograft rejection[75] and enhanced tumour growth[76], all of which depend on intact T cell function. A feature common to all these injured states is the presence of wounded tissue. Not only is there evidence to suggest that the incidence of post-traumatic immunosuppression is related to the extent of the injury, but also that there is a direct relationship between the extent of injury and the incidence of post-traumatic septic complications and mortality[76–79]. Patients who became septic after burns all showed immunosuppressive serum preceding or coinciding with the septic episode[77]. A vicious circle may occur in which immunosuppressive factors initiate and propagate the systemic inflammatory response and host infection, leading to the production of new immunosuppressive factors.

If the wound is, indeed, a potential source of factors that contribute to alterations in immune function, it might be expected that the extracellular wound fluid that collects at the site of repair would be rich in such factors. Support for this hypothesis is provided by a number of *in vivo* studies examining the effect of parenterally administered extracellular wound fluid in normal animals. Intraperitoneal administration of wound fluid collected from 10-day-old wounds inhibits *in vivo* allogenic responses, as assessed by skin graft rejection, compared with autologous serum injection[80]. Also, *in vivo* administration of wound fluid impairs the immune responses to sepsis[81].

The wound factors responsible for these immunosuppressive effects have only been characterized incompletely. Prostaglandins and many of the cytokines produced by inflammatory cells have immunosuppressive qualities. PGE_2, a metabolite of the arachidonic metabolism, has an immunoinhibitory effect on cell-mediated immunity[82]. PGE_2 production by mononuclear cells occurs after burns and traumatic injury[83]. Increased production of PGE_2 adversely affects antigen presentation by macrophages via a depression of Ia antigen expression (murine MHC class II equivalent) in a dose-dependent manner. In addition, PGE_2 exerts a downregulatory effect on TNF-α and membrane IL-1 expression by macrophages[84], thereby interfering further with a membrane protein that is important for adequate antigen presentation. This is thought to be mediated through a PGE_2-induced increase in intracellular adenosine 3′, 5′-cyclic monophosphate (cAMP) levels. A similar mechanism may occur in the depression of IL-2 production by T lymphocytes[85]. In septic injury, decreased T lymphocyte proliferative activity is caused, at least in part, by impaired intracellular calcium ion^{+} mobilization. This may be a consequence of PGE_2 activation of the secondary messenger cAMP, which can antagonize calcium signalling in T cells[86,87]. In addition, it appears that PGE_2 is an important costimulator for the shift of type 1 towards type 2 T helper lymphocyte phenotype, leading to decreased IL-2 and IFN-γ activity[88].

The presence of other serum depressive factors known as 'suppressive active (glyco-)peptides' has been reported in the serum of patients with burns or other trauma. These peptides may suppress T and B cell proliferation and inhibit IL-2 production by concanavalin A-stimulated peripheral blood T lymphocytes. The molecular weight of these immunosuppressive substances ranges between 2000 and 600 000 Da, but the best described have a molecular weight of less than 20 000 Da[89].

Proinflammatory cytokines, such as IL-1, IL-6 and TNF-α, are derived mainly from activated macrophages and, when produced in excessive amounts, contribute to the immunosuppression observed following trauma[90,91]. Release of these endogenously derived proinflammatory mediators is currently thought to be responsible, at least in part, for the early activation of the acute phase response, and to play a central role in the beneficial and adverse sequelae of infection and injury[92].

Increased levels of TGF-β, known mainly as a growth factor involved in tissue repair mechanisms, are associated with impaired T cell function and immunosuppression during sepsis[93] and after injury[94]. Similarly, levels of IL-10, a cytokine shown to inhibit type 1 T helper cell and macrophage function, are raised in patients soon after surgery[95]. Some investigators, however, have demonstrated decreased IL-10 production by splenocytes isolated from septic and injured animals[96]. Neutralization of endogenous IL-10 increases TNF synthesis and mortality in animal models of endotoxaemia[97] and peritonitis[98], but increases survival in a model of pneumonia[99]. Recently, Hauser *et al.*[100] reported increased levels of IL-10, but not of IL-4 or TGF-β_1, in human soft tissue haematomas associated with fracture, providing further evidence that immune modulatory factors may collect at the site of injury[100]. The exact role of IL-10 in post-traumatic and septic immunosuppression, however, remains unclear. It should be emphasized that these cytokines may not only mediate deleterious effects on host integrity during the systemic inflammatory response but also represent important regulators of the normal immune response. Also, both experimentally and clinically, alterations in cytokine concentrations and activities often represent both the cause and effect of immunosuppression after injury, making the assessment of their role in the immune response difficult.

Soluble receptors to TNF-α and other proinflammatory cytokines have been isolated in the circulation of patients after trauma and are thought to represent a regulatory tool for the inhibition of the actions of these cytokines[101]. Soluble forms of cytokine receptors seem to be structurally identical to the extracellular portion of the cytokine-binding domains of these receptors[102,103]. This may be an example of autoregulation of the immune system. Whether the expression of these soluble receptors results in pathological immunosuppression or, more likely, improves post-traumatic immune defence by neutralizing excessive proinflammatory cytokines, remains unclear. It appears that soluble mediators of cellular interactions may exert beneficial or detrimental effects on host defence function, depending on their concentrations and their interplay within the cascade of cytokine reactions during the inflammatory response.

There is, therefore, strong support for the hypothesis that overspill of the wound environment into the general circulation has a role in the induction of post-traumatic immunosuppression. Not only is a number of potent immunosuppressive factors present in the wound, but there is evidence of alteration in immune activity at sites remote from the wound. Further support for this hypothesis is provided by the fact that the appearance and degree of post-traumatic immunosuppression correlates with the extent of the initial injury. In addition, it is well known that the early removal of damaged and/or infected tissue can prevent or diminish immunosuppression after injury[104]. It may well be that, in the presence of major tissue damage and the need for extensive wound repair, the processes that are normally limited to the site of healing spill into the general circulation and have multiple, possible undesirable, consequences on normal immune responsiveness.

Table 2 Lymphocyte dysfunction after injury

Impaired CD4^{+} T cell activity
Impaired CD8^{+} T cell activity
CD4^{+}:CD8^{+} ratio reduced
Appearance of immature T cells
T helper lymphocyte shift from type 1 (tumour necrosis factor β, IL-2, interferon γ) to type 2 (IL-4, IL-5, IL-6, IL-10)
Loss of recall antigen responses (anergy)
Impaired B cell function and immunoglobulin production
Decreased natural killer and lymphokine-activated killer cell activity

IL, interleukin

Lymphocyte function following systemic injury

Injury not confined to the initial site of insult affects the immune response via both cellular and humoral immunity (*Table 2*). This in turn may increase susceptibility to infection and death from sepsis[73,105].

T lymphocyte function following injury

The first evidence that the cell-mediated immune response was impaired in traumatized patients was published 50 years ago[106]. After injury, alterations of T lymphocyte immune function may be a result of lymphocyte subpopulation changes, as assessed by differential expression of surface markers, as well as a result of cell activity changes. Alteration of cell activity may be assessed by the response of lymphocytes to *in vitro* activation by mitogen, lymphokine synthesis, and expression of surface markers and receptors.

Decreased lymphocyte proliferation in response to mitogenic stimulation occurs after surgical procedures, accidental trauma, burns and haemorrhage[107–109]. This effect usually lasts for several days after injury, despite maximum resuscitation and normal recovery[110,111]. Both clinical and experimental studies have demonstrated that this impairment of T cell proliferative response is associated with an increased susceptibility to infection and death[105,111,112].

Lymphocyte subtypes. Lymphocyte function is determined in large part by the antigens displayed on the cell surface. These surface antigens control cellular interactions and regulate biochemical activities in the cytoplasm, thereby determining the cell's functional response. The specific nature of the T cell response appears to be controlled by the T cell receptor–CD3 complex. The coreceptor molecules CD4 and CD8 bind MHC class II and class I molecules respectively, and act synergistically with the T cell receptor in signalling, resulting in an increase in the sensitivity of T lymphocytes to antigen[113,114].

Following injury, alterations in lymphocyte numbers and subset proportions have been described in different lymphoid compartments. Lymphocytes from bone marrow, peripheral blood, spleen and thymus are decreased after thermal injury, but lymph nodes draining a wound contain a severalfold increase in their number of lymphocytes[15]. Immune alterations after thermal injury and decreased lymphocyte numbers in different organs after injury may be due, at least in part, to a redistribution of the lymphocyte pool. Following traumatic injury[79] and burns[116], the absolute number of lymphocytes decreases in the circulation, the decrease in the proportion of $CD4^+$ lymphocytes being greater than that of $CD8^+$ lymphocytes. Thus, there is a shift from the normal ratio of $CD4^+$ cells to $CD8^+$ cells (2:1 in human circulation), to a greater proportion of $CD8^+$ T cells. In rodents, the injection of $CD8^+$ T cells predisposes to increased mortality when the animals are subjected to septic insult[117]. The *in vivo* administration of a monoclonal antibody directed against such $CD8^+$ cells in burned animals improves survival following a bacterial challenge. This finding further substantiates the important role of $CD8^+$ T cells in burns. In contrast, others have found a relative decrease in the $CD4^+:CD8^+$ ratio only in animals with infection; this was not present in thermal injury without infection[118]. This is consistent with results in patients with trauma[119] and in haemorrhaged mice[20]; neither show changes in the numbers or proportions of $CD8^+$ or $CD4^+$ cells. At present it remains controversial whether injury is associated with altered $CD4^+:CD8^+$ ratios. There may be a difference between burned patients, and patients after non-thermal injury and haemorrhage. Also, it is not clear whether this alteration of $CD4^+:CD8^+$ ratio is cause or effect in the context of infection. Feeney *et al.*[121] reported decreased numbers of $CD4^+$ and $CD8^+$ cells in acutely ill patients admitted to the intensive care unit for medical or surgical reasons. However, depression of T cell numbers was unpredictable and did not correlate with severity of illness, predicted mortality rate or actual mortality rate.

As naive $CD4^+$ T lymphocytes differentiate, they become either type 1 or type 2 T cells, characterized by the pattern of lymphokines they secrete (*Fig. 3*). Type 1 helper cells transcribe and translate messenger RNA (mRNA) for TNF-β, IFN-γ and IL-2, and regulate T cell-mediated macrophage activation. The counterpart of type 1 subgroup is the type 2 subgroup. Through the elaboration of IL-4, IL-5, IL-6 and IL-10 (but not TNF-β, IFN-γ or IL-2), type 2 helper cells are involved in B cell differentiation and the humoral immune response.

Following injury, in addition to decreased numbers of T helper cells, there is a shift in the type 1:type 2 T helper cell balance towards a dominance of type 2, leading to downregulation of cell-mediated and, in some cases, upregulation of antibody-mediated immunity[122–124]. *In vivo* treatment with IL-12, a cytokine that induces a shift from the type 2 towards the type 1 T helper lymphocyte phenotype, increases survival after major trauma. This treatment with IL-12 is accompanied by increased IL-2 and IFN-γ and decreased IL-4 production by splenocytes[122,125].

Fig. 3 Stages of activation of $CD4^+$ T lymphocytes. Naive $CD4^+$ cells are thought to pass through an intermediate stage, the immature effector T cell (T_H0). T_H0 cells express some effector functions of both type 1 and type 2 helper cells. The T_H0 cells then differentiate into type 1 or type 2 $CD4^+$ T cells, characterized by the pattern of lymphokines they secrete. Selective activation of type 1 cells leads to cell-mediated immunity, whereas selective formation of type 2 cells promotes humoral immunity. IL, interleukin; IFN, interferon; TNF, tumour necrosis factor

The response to traumatic and thermal injury in humans involves the appearance in the peripheral blood of immature T cells that may express T6, T9, T10 and Ia1 surface antigens. These cells may be present in quantities otherwise seen only in malignant disease[126]. During infection, lymphocytes harvested from burned animals demonstrate altered intracellular metabolism, including rate of glucose and amino acid utilization, and decreased levels of adenosine deaminase, an immunologically important enzyme for lymphocyte activity[127].

Lymphokines. Ex vivo, the T cell receptor complex may be stimulated by different mitogens such as phytohaemagglutinin or concanavalin A, leading to effector responses by all T cells bearing this T cell receptor complex[114]. Mitogen and/or antigen-activated T lymphocytes produce IL-2. T cell activation, on the other hand, requires synthesis of regulatory cytokines, mainly IL-2, and expression of the corresponding cytokine receptor[128]. Experimentally, exogenous IL-2 improves cell-mediated immune response against infection[129]. Following injury, both human and animal studies have shown decreased IL-2 synthesis and IL-2 mRNA expression by T cells[107–109]. This diminished T cell ability to excrete IL-2 may be noted as long as 60 days after injury[130]. In burned mice the principal cellular abnormalities that result in altered T cell activation and IL-2 production lie downstream of the initiating signal transduction events and before IL-2 gene transcription[109,110]. A defect that involves the membrane receptors as well as the cytoplasmic cascade may explain why decreased IL-2 secretion can be only partially reversed by direct stimulation of the cytoplasmic components[131]. It has been suggested that the defect of the intracellular signal transduction pathway occurs at the calcium ion signal step and/or in the upstream signalling component effecting protein tyrosine phosphorylation[132].

For normal T cell function, IL-2 receptor expression and the cytoplasmic cascade following receptor activation appear to be as critical as the expression, synthesis and excretion of IL-2 itself[128]. However, results from studies investigating the effect of injury on IL-2 receptor expression are conflicting. Following injury, expression of the IL-2 receptor is reported to be decreased[83,131], increased[133] or unchanged[110,134].

After haemorrhage the production of other lymphokines, including IL-3, IL-5 and IL-6, is depressed[108,120]. IL-3 supports the survival, growth and differentiation of multipotential stem cells, and of erythroid and myeloid progenitor cells. Thus, the depression of IL-3 may have a direct effect on a variety of different cellular components involved in cell-mediated immunity, including the recruitment and maturation of monocytes and lymphocytes. IL-5 depression, similarly, may have a direct immunosuppressive effect on lymphocyte response to injury, as IL-5 stimulates B lymphocyte growth and antibody production, and enhances eosinophil differentiation. The proinflammatory cytokine IL-6 is produced early in the response to injury[90]. As IL-6 plays an important role in B cell activation, depression of this lymphokine may have important implications for the development of a competent humoral response. This is in keeping with depressed B cell responsiveness after injury[135].

IFN-γ activity is reported to increase or decrease after haemorrhage and to decrease after accidental injury[108,120]. IFN-γ is recognized as an important upregulator of macrophage function and, depending on the condition, may either stimulate or suppress B cell proliferation and differentiation. The marked decline in the capacity of T cells to produce IFN-γ after injury would be expected to lead to the impairment of macrophage activation as well as activation of cytotoxic T cells. There is evidence that the expression of human leucocyte antigen (HLA)-DR receptors on monocytes, which is coded by the MHC class II and needed for antigen presentation to T cells, decreases after trauma[136]. In addition, depressed levels of IFN-γ result in impaired T cell response to antigen and diminished monocyte antigen presentation[10].

Lymphocytes and nitric oxide. The activation of cytokine-inducible nitric oxide synthase (iNOS) during septic injury leads to the production of large quantities of nitric oxide, a recently discovered radical and biological mediator which can be toxic. Lymphocyte proliferative activity is impaired by macrophage-derived nitric oxide[137]. After burn injury, suppressed lymphocyte proliferation improves after *in vitro* addition of *N*-monomethyl-L-arginine (L-NMMA), a competitive inhibitor of NOS. This indicates a possible lymphocyte immunosuppressive role for nitric oxide in major injury[138]. When a panel of cloned T cells was examined, it appeared that type 1 T helper cells could be induced to produce nitric oxide, whereas type 2 T helper cells could not[139]. Secretion of IL-2 and IFN-γ by the cloned type 1 T helper cells was enhanced in the presence of L-NMMA, but was significantly inhibited by the addition of the nitric oxide donor, S-nitrosyl penicillamine, suggesting that nitric oxide may exert a self-regulatory effect on type 1 T helper cells. Other authors have proposed that nitric oxide may support a type 2 lymphocyte immune response. Mutant mice, lacking in iNOS, develop a significantly stronger T helper 1 type immune response, show reduced non-specific inflammatory response to carrageenin and are resistant to lipopolysaccharide-induced death[140].

In an animal study investigating the role of nitric oxide in the local inflammatory response, treatment with L-NMMA caused a significant reduction in T cell activity, measured by the production of IL-2 and IFN-γ, and T cell proliferation[141]. This suggests that nitric oxide may promote T cell activity in this model. It has also been demonstrated that nitric oxide is produced by mitogen-stimulated human peripheral blood mononuclear cells and that its production is essential for optimal proliferation[142]. The apparent contradiction in the effect of nitric oxide on T cell activity may be well due to the dual effect of nitric oxide on T cell proliferation. Low nitric oxide concentrations may be required for a normal T cell response, whereas high concentrations may inhibit cellular proliferation. A similar dual role for nitric oxide in the regulation of cell activity has been reported in studies investigating the effect of nitric oxide on protein synthesis by mesenchymal cells. Low nitric oxide concentrations appear to promote collagen synthesis, whereas higher levels inhibit protein and collagen production[143,144].

B lymphocyte function following injury

B lymphocyte-derived immunoglobulins mediate the humoral component of the specific immune response. The proportion of B cells that actively produce immunoglobulins is small, usually less than 1 per cent of the total number of plasma cells. After systemic infection there is amplification of this proportion, with the percentage of the total plasma cell repertoire specifically directed in this manner being as high as 10 per cent. Antibodies protect the host from infection by pathogen neutralization, opsonization or complement activation. Antibody response to antigens, however, requires T cell help[145]. B cells are recognized by T helper cells when antigen bound by surface immunoglobulins is internalized and returned to the cell surface as peptide bound to MHC class II molecules. The interaction of an antigen binding B cell with an armed T cell leads to the expression of the B cell stimulatory CD40 ligand on the helper T cell surface and to the secretion of stimulatory cytokines[146]. B cell differentiation is regulated mainly by the type 2 T helper lymphocyte phenotype, characterized by the expression of IL-4, IL-5 and IL-6[147]. Although armed T helper cells are required for B cell responses to protein antigens, certain bacterial products, such as lipopolysaccharide, can induce B cell proliferation and differentiation in the absence of T cells[148].

The plasma cell antibody response may be affected at many steps in the B cell activation process. Alterations in B cell antigen presentation may result in decreased T cell help via the MHC class II antigen and impaired release of T cell-derived lymphokines. Decreased numbers of B cells capable of developing into immunoglobulin-synthesizing plasma cells will result in impaired antibody response. Like the overall host defence, B cell maturation and B cell response to infection have been shown to be affected by injury.

B cell differentiation may be assessed by examining the spontaneous and cytokine- or mitogen-induced immunoglobulin production by B cells *in vitro*. Spontaneous production of immunoglobulin (Ig) G in culture by B lymphocytes isolated from the peripheral blood of patients after trauma is increased[149] or unchanged[150], while spontaneous production of IgM is decreased[150] or unchanged[149]. Pokeweed mitogen (PWM) or *Staphylococcus aureus* Cowan I antigen-induced secretion of IgG and IgM has also been variously reported as enhanced or reduced. *In vitro* addition of indomethacin has no effect on decreased PWM-induced IgM and IgG secretion, suggesting that the suppressive effect is not PGE_2 mediated[150]. However, the addition of normal T lymphocytes or supernatants from antigen-stimulated T cells to B cells enhances the antibody response to PWM, suggesting that the impaired B cell response after trauma may be due to failure of T cell help[150].

The spontaneous expression of CD23, a B lymphocyte activation antigen, is reduced on B cells from burned patients[133]. Also, decreased antibody response to viral immunizations occurs in children with blunt trauma[151]. DNA synthesis in B lymphocyte mitogen-stimulated cultures, however, is increased in burned patients, but decreased in those with trauma[150].

Major trauma and minor injury or stress in mice results in a gradual fall in the level of B lymphocytes, with the maximal drop 2 h after the operation or handling procedure. Numbers return to normal within 24 h of both minor and major trauma[73]. In healthy adult patients undergoing nephrectomy as transplant donors, no changes in immunoglobulins are found, but total B cell numbers fall[152]. Haemorrhage causes a decrease in serum immunoglobulin levels, as well as decreased numbers of B cells secreting antibody[135]. There may be a change in B cell repertoires after haemorrhage, so that in the week after haemorrhage there are fewer pre-B cells present potentially to become plasma cells producing antibody against bacterial antigens. Thermal injury is associated with decreased serum IgG levels[153]. IgA and IgM levels are not affected except when burn eschar is infected with fungus, when IgM levels rise.

It appears that the function of antibody-producing B lymphocytes is variably affected by traumatic injury. Many reported effects may not be discussed in isolation, without examining changes in T lymphocyte function. Because B cell function is directly affected by cytokine production by macrophages and T lymphocytes, as well as by interactions with antigen-specific helper T cells, abnormalities in any of the steps in the B cell activation cascade may result in a diminished B cell response. In this way impaired B lymphocyte function will be secondary to alterations of T lymphocyte and macrophage function following trauma.

Therapeutic immunomodulation

Therapeutic modulation of the immune system following injury ranges from basic interventions designed to restore homoeostasis with aggressive resuscitation and nutritional support to the latest state-of-the-art manipulations of immune cell activity and its products. The following focuses on some approaches that may currently be undertaken to alter host immune function in the clinical setting.

Nutrition

The relationship between nutrition and immunity has been investigated extensively in the past. Acute protein calorie malnutrition is known to depress cell-mediated immune response[154]. Nutritional repletion can restore some of the abnormalities, as assessed by total lymphocyte count, mitogen responsiveness and skin-test reactivity. The hypermetabolic state associated with acute injury imposes a significant strain on the patient's nutritional reserves, with a substantial effect on the immune system. Immediate nutritional support after trauma reduces the incidence of septic complications and mortality[155]. The route of administration and composition of nutritional formulas seem to be important, with enteral feeding apparently superior to parenteral nutritional support, leading to improved cell-mediated immune function, reduced septic complications and shorter hospital stay[156,157]. In addition, early rather than delayed, and supplemented rather than standard, diets are associated with better outcome[158–161]. There is evidence that supplemented enteral nutrition commenced before operation has some benefits over solely postoperative feeding[162].

Several specific supplemental nutrients have been identified recently as offering specific immunomodulatory properties. Often these nutrients are used in amounts well in excess of normal nutritional requirements and so they are said to possess a 'pharmacological' effect, in order to differentiate the situation from standard nutritional use. Such nutrients include arginine, glutamine, ω-3 polyunsaturated fatty acids and nucleotides.

In animal studies, arginine supplementation improves survival after burns and intra-abdominal sepsis[163,164]. In addition, exogenous arginine improves the healing of skin wounds in both rodents and humans[165,166]. Lymphocyte blastogenesis and T helper cell numbers are increased in patients after surgery who receive arginine supplementation[167].

Glutamine is the most abundant amino acid in the body, accounting for approximately 20 per cent of the total circulating free amino acid pool and for more than 60 per cent of the free intracellular amino acid pool. It is an important vehicle for nitrogen transfer between tissues. Glutamine is also a regulator of protein synthesis and an essential precursor for nucleotide biosynthesis in all cells. It serves as an energy fuel for the gut mucosa and other rapidly dividing cells, such as fibroblasts, lymphocytes and epithelial cells[168]. Trauma, severe illness and sepsis are followed by a rapid fall of muscle and plasma glutamine levels[169,170]. For this reason the clinical application of glutamine has been pursued and some efficacy has been shown in clinical outcome, including improved postoperative nitrogen balance[171]. In patients after bone marrow transplantation, a reduced incidence of infection and a shortened hospital stay are associated with glutamine supplementation[172].

The amount and type of dietary lipids can profoundly influence immune response and resistance to infection. Lipids become incorporated into phospholipids of cell membranes and other components within cells, thereby influencing structural integrity, transport systems, membrane fluidity, receptor expression and cell–cell interactions. Diets high in ω-3 polyunsaturated fatty acids (found in fish oils) appear to have some beneficial effects on immunosuppression following injury, and have been reported to be superior to conventional diets containing mainly ω-6 polyunsaturated fatty acids (found in vegetable oils)[173]. Although there is controversy concerning the immunomodulatory mechanisms of such diets, a reduction in immunosuppressive eicosanoid release (e.g. PGE_2) and an altered profile of inflammatory cytokines (e.g. TNF-α, IL-1, IL-6) seem be responsible for the observed phenomena.

Ribonucleic acids are essential for cellular turnover and protein synthesis. In conditions of severe stress, dietary supplementation with nucleotides appears to reverse some aspects of immunosuppression[174,175].

Several of these immunostimulatory dietary components have been combined to evaluate their total immunological and metabolic effects in the clinical setting. In the treatment of severely burned patients a low-fat enteral diet supplemented with 0·4 per cent arginine, 0·25 per cent cysteine and 0·5 per cent ω-3 fatty acids reduces wound infection and length of stay, compared with other standard enteral formulations[176,177]. In another prospective trial, surgical patients undergoing operation for upper gastrointestinal malignancy were randomized to receive either a supplemented (arginine 12·5 g/l, RNA 1·25 g/l and ω-3 fatty acids 1·7 g/l) diet or a standard enteral diet after surgery[161]. Septic complications and length of hospital stay were reduced in the supplemented group. Similar results, including increased numbers of lymphocytes, decreased infection rates and length of stay, have been documented by others[158,178].

Cytokine modulation

Immune dysfunction in states of profound stress is characterized by impaired balance of immunosuppressive and counter-regulatory influences. Much effort has been expended in interfering with early inflammatory events thought to set the stage for the subsequent generalized inflammatory response. Immunomodulatory therapy has focused on strategies designed to inhibit TNF, IL-1 and IL-6, using cytokine antibodies, receptor antagonists or soluble receptors. Anticytokine therapy has been successful in animal models. In clinical studies, however, results are less convincing[179,180]. No improvement in survival has been noted; indeed an increased mortality rate was reported in patients receiving high doses of recombinant human TNF receptor[181]. Use of an IL-1 receptor antagonist, however, has yielded some promising early results in humans[182]. In a randomized human phase III study increased survival has been documented, but only in a retrospectively defined subset of high-risk patients[183]. Distinct survival advantages have yet to be demonstrated by randomized prospective trials using anticytokine therapy in the clinical setting.

Granulocyte colony-stimulating factor (G-CSF) for sepsis prophylaxis in neutropenic patients (e.g. patients receiving chemotherapy for cancer) is well established. However, the use of G-CSF following injury is experimental. In patients with burns, leucocyte function improves and white blood cell count is increased after G-CSF treatment[184]. Lipopolysaccharide-induced release of proinflammatory cytokines (TNF-α, IL-1β) from blood cells was attenuated in volunteers pretreated with G-CSF[185], suggesting that there may also be some prophylactic properties of G-CSF against sepsis in non-neutropenic patients.

Immune suppression following injury is reflected in polarization of the helper T cell activity with a shift in the type 2 T helper cell direction[122,124]. Impaired type 1 T helper cell activity is reflected in decreased synthesis of IL-2 and IFN-γ. The inability to produce adequate amounts of IL-2 results in an incomplete proliferative T cell response to antigenic stimuli, whereas the lack of IFN-γ results in inefficient macrophage antigen presentation[10]. Attempts have therefore been made to modulate the cell-mediated immune response by administration of these lymphokines to animals and humans. The administration of IL-2 appears to enhance survival in animals with intra-abdominal sepsis. It is most effective when given at the site of infection and probably acts by stimulating local host defences[186]. There are as yet no reliable data from human studies using IL-2 as an exogenous immunostimulatory agent after injury.

Exogenous IFN-γ increases resistance to intra-abdominal sepsis, and improves survival after trauma and haemorrhagic shock[187]. In humans, IFN-γ reverses the trauma-induced suppression of MHC class II HLA-DR antigens on macrophages[188]. However, no clear benefit in sepsis-related morbidity or mortality has been demonstrated in patients given IFN-γ[189]. Recently, treatment with IL-12, a cytokine that induces a shift from the type 2 towards the type 1 T helper lymphocyte phenotype, has been reported to increase survival after major trauma in animals[125]. IL-12 treatment resulted in increased IL-2 and IFN-γ production by splenocytes.

Non-steroidal anti-inflammatory drugs

PGE_2 production from arachidonic acid by activated monocytes–macrophages is proposed as one of the most critical immunosuppressive pathways after injury[188], affecting both humoral and cellular immune function. After severe trauma, upregulated PGE_2 synthesis lasts for as long as 21 days[83]. Cyclo-oxygenase-inhibiting non-steroidal anti-inflammatory drugs (NSAIDs), such as ibuprofen or indomethacin, restore some of the immunosuppressive effects following trauma. In animals, ibuprofen and indomethacin are effective in reducing PGE_2, preventing depressed T cell proliferation[86], improving antigen presentation by macrophages and synthesis of IL-1 and TNF, and maintaining lymphocyte IL-2 and IFN-γ production[190,191]. Their use is associated with improved organ function and survival following septic shock[192,193]. In septic burned rats, however, ibuprofen decreases the survival rate[194]. In patients with major trauma or following operation, indomethacin seems to improve the cellular immune response, including increased IL-2, IL-1 and TNF-α release[195,196]. A significant increase in the CD4:CD8 ratio was shown by Gogos *et al.*[197]. Improvement of haemodynamic and pulmonary function in septic patients by ibuprofen treatment has been reported by others[198]. Deterioration of renal function, found in some animal studies, and integrity of the gastric mucosa are concerns when NSAIDs are used routinely in the compromised patient. Adequate fluid resuscitation and cytoprotective agents may ameliorate certain of these effects, but the use of NSAIDs cannot be endorsed unequivocally. Further studies are required.

Thymomimetic agents

Thymic hormones promote the cytokine-mediated regulation of T cell development in precursor cells and also the proliferative response of mature T cells in the periphery[199]. Different compounds, including the synthetic thymomimetic purines, such as isoprinosine and methylinosine monophosphate (methyl-IMP), and the pentapeptide TP-5, have been used in the past to modulate cellular immune function[200,201]. Further insight into the effect of thymic hormones on immune function and tissue repair mechanisms was obtained from studies using congenitally athymic mice, thymectomized adult animals and animals treated with thymic hormones[32,33,40]. Thymic hormones and CD8$^+$ T cells that are generated in the thymus downregulate the early cellular events of wound repair, leading to decreased collagen deposition and reduced wound mechanical strength. Methyl-IMP augments lymphocyte responses to T lymphocyte mitogens in rodents and humans. Also, delayed-type hypersensitivity is increased after methyl-IMP administration. Isoprinosine reverses *in vitro* immunosuppressive effects following trauma and burns[199].

TP-5 restores the *in vitro* lymphocyte proliferative response as well as the delayed-type hypersensitivity response after major surgery[202]. However, T cell receptor protection (CD3 and CD4) and restoration of IL-2 synthesis are not achieved with TP-5 alone. When TP-5 is combined with indomethacin, *in vitro* testing of lymphocyte function shows improved T cell reactivity compared with TP-5 alone[203]. These results indicate that simultaneous cyclo-oxygenase inhibition and T cell activation can enhance cell-mediated immune mechanisms following surgical trauma. TP-5 decreases mortality in burned[204] and septic[205] animals. In critically burned patients, however, a randomized trial failed to demonstrate improved mortality or rate of septic complications[206]. Overall, the clinical relevance of these observations remains doubtful, as data demonstrating improved morbidity and mortality in humans are lacking.

Immunoglobulins

The demonstration of impaired humoral immunity in sepsis and following major injury gave rise to numerous studies using immunoglobulins in an attempt to provide the patient with higher titres of antibodies against bacterial endotoxins and exotoxins, with or without increased opsonic activity. In addition, immunoglobulins may synergize with β-lactam antibiotics due to their content of antilactamase antibodies[207]. Both experimental and clinical trials suggest a protective effect of intravenous immunoglobulin preparations against various infections, using 5S and 7S immunoglobulin, IgG, IgM, IgG with IgM and IgA, and *Pseudomonas* immunoglobulin[208–215].

The beneficial effects of immunoglobulin treatment may be seen first through a reduction in the number of infectious and septic complications in surgical and polytraumatized patients and, second, through a reduction in the duration of mechanical ventilation and of treatment in the intensive care unit in patients with infectious complications after surgery. However, with regard to the ultimate endpoint of all sepsis and trauma trials – reduction in MODS and mortality – the results of most controlled clinical trials have been disappointing. In patients with severe postoperative sepsis, however, Dominioni *et al.*[209] have reported a reduction in the mortality rate from 67 to 38 per cent with IgG therapy. In a different study, in which E5, a murine immunoglobulin (IgM) antilipid A monoclonal antibody, or placebo was given to patients with suspected Gram-negative sepsis, the overall mortality rate was comparable between the two groups. In the subsets of patients with confirmed Gram-negative septic shock, mortality was slightly higher in the treated than in the placebo group, but significantly lower in treated patients with sepsis but no shock[211]. On the other hand, when HA-1A, a predominantly human IgM antiendotoxin monoclonal antibody, was used, the subgroup with Gram-negative bacteraemia, both with and without shock, had a lower mortality rate[215]. However, a subsequent multicentre trial with HA-1A was suspended when an interim analysis of data revealed a slight but not significant increase in mortality in non-bacteraemic patients[214]. A truly beneficial effect of immunoglobulin treatment in trauma and sepsis still remains to be proven.

Other therapeutic approaches and conclusion

A great variety of agents is being evaluated in experimental animals. Some, such as glucan (a potent macrophage stimulant)[216], ketoconazole (a thromboxane synthase inhibitor)[217] and antithrombin III[218], have shown promising results in clinical trials. More recently, nitric oxide, thought to play an important role in the septic state, has been studied extensively in animals and humans. Inhibitors of NOS have been used to reverse the haemodynamic changes caused by sepsis, but results are conflicting[219,220]. Nitric oxide inhibition causes an increase in mean arterial blood pressure and systemic vascular resistance, as well as a decrease in cardiac output and heart rate in patients with sepsis[221]. However, organ perfusion may be decreased by nitric oxide inhibition, leading to organ damage and increased mortality[222,223]. Although increased nitric oxide synthesis may cause hypotension in septic shock, nitric oxide also modulates the immune response, inhibits platelet and granulocyte adhesion, and seems to be an important mediator in the nervous system. So depending on dose and location, nitric oxide may exert both beneficial and detrimental effects on host integrity[224,225]. Also, because pure selective inhibitors of the different NOS isoforms (iNOS, neuronal constitutive NOS, endothelial constitutive NOS) are not available, further work needs to focus on the development of selective inhibitors which, when given at the right time and dose, may have beneficial effects on the outcome of septic states. In contrast to increased levels of nitric oxide in sepsis, nitric oxide production after trauma is decreased, which may contribute to increased susceptibility to infection[226]. Clearly, interventions affecting nitric oxide physiology must carefully take into account the differential role that nitric oxide may play in the immune response.

Of the different approaches currently being undertaken to modulate immune function following injury, only some can be recommended unequivocally: (1) early and complete resuscitation with restoration of organ perfusion; (2) aggressive wound debridement, particularly of burn wounds; (3) drainage of any septic focus and use of appropriate antibiotics; and (4) early enteral nutrition with consideration of specific nutritional supplements, such as arginine, glutamine, ribonucleic acids and ω-3 polyunsaturated fatty acids.

Early host support to modulate immune function after injury seems to be critical for the outcome after severe trauma. The basic scientific fields of cellular and molecular biology, immunology and medical genetics are increasing the understanding of immune dysfunction after injury and during sepsis, and are providing clinicians with new therapeutic tools. To date, however, most clinical trials of novel agents to treat sepsis and injury-related immunosuppression have failed to show clinical efficacy. This has occurred despite considerable animal data suggesting a positive therapeutic benefit.

Review

Non-operative management of blunt hepatic trauma

E. H. CARRILLO*, A. PLATZ†‡, F. B. MILLER*, J. D. RICHARDSON* and H. C. POLK JR*†

**Department of Surgery and †Price Institute of Surgical Research, University of Louisville School of Medicine, Louisville, Kentucky, USA and ‡Department of Surgery, University of Zurich, Zurich, Switzerland*

Correspondence to: Dr E. H. Carrillo, University of Louisville Department of Surgery, Louisville, Kentucky 40 292, USA

Background Non-operative management is currently considered the treatment of choice in over 50 per cent of adult patients with blunt liver injury. This report reviews the criteria for non-operative management and its potential downside.

Methods English language publications were reviewed.

Results Most reports from major trauma centres in the USA support the non-operative treatment of patients with blunt liver injury if well established criteria are met. Using such criteria, non-operative treatment is successful in 50–80 per cent of cases. Adjunctive radiological techniques may be helpful in managing some complications of non-operative treatment.

Conclusion Non-operative management is safe in haemodynamically stable patients with blunt liver injury. Computed tomography (CT) of the abdomen is extremely useful to document the extent of the damage and the presence of associated injuries, but it is not possible, based on CT alone, to predict failure; careful physiological monitoring in selected patients is indicated to avoid catastrophic complications.

The liver is the most commonly injured abdominal organ after penetrating and blunt trauma[1,2]. The widely variable nature of the injury contributes to the extensive literature on this subject and it is the main reason for the number of operative alternatives[3]. Over the past 10 years, there has been a dramatic change in the management of hepatic injury, specifically its non-operative management. Even though non-operative treatment has become the standard of care in children, its use in the adult population is surrounded by controversy. However, this approach, initially met with scepticism, is becoming the standard method of care in major trauma centres in the USA[1,4–7]. The main reasons behind the success of this approach include: (1) better imaging techniques, (2) clinical experience from abbreviated laparotomy and planned reoperation ('damage control')[8–10], and (3) a better understanding of the natural history of liver injury (i.e. bleeding, healing and complications).

At the University of Louisville there has historically been a great deal of interest in the management of hepatic injury[3,9–18] and, using that experience as well as an analysis of the current literature, the authors will: (1) review the surgical anatomy of the liver and its implications for the diagnosis and non-operative treatment of injury, (2) describe the current classification of liver injury based on organ injury scaling, (3) analyse the complications of non-operative management and their relationship to morbidity and death, and (4) describe the current criteria used in this non-operative treatment. Penetrating injury and surgical management of specific hepatic injuries are not discussed because such management has been more consistent over time.

Surgical anatomy

For the trauma surgeon, knowledge of the vascular supply of the liver and its relationship to the different segments and lobes is crucial in determining the best surgical alternatives at operation. After birth the umbilical vein obliterates, leaving the liver with two nutrient sources of blood, the splanchnic circulation through the portal vein and the hepatic artery. The dual blood supply merges in the hepatic sinusoids and is collected from this site into the hepatic veins that join the inferior vena cava (IVC) behind the liver. The blood supply divides the liver into right and left lobes, which cleave in a plane that passes from the bed of the gallbladder to the IVC. In the presence of active haemorrhage, surgical exposure of the hepatic veins is extremely difficult, but has become more feasible as a result of techniques developed in liver transplantation. The segmental distribution of the blood supply further divides the right lobe into anterior and posterior segments, and the left lobe into medial and lateral segments, along with the quadrate lobe anterior to the porta hepatis and the caudate lobe posterior to the portal vein[19]. The liver is surrounded and secured by numerous ligamentous structures, including the right coronary ligament, the right triangular ligament, the left coronary ligament, the left triangular ligament (which fuses as a single structure at the tip of the lateral segment of the left lobe to form the appendix fibrosa hepatis), and the falciform ligament (which contains the obliterated umbilical vessels in the ligamentum teres hepatis[20]). Treatment of hepatic haemorrhage often requires mobilization and elevation of the liver by ligamentous division.

Physiology

The main function of the liver is filtration, regulation of metabolic substrates, specific protein synthesis for

Paper accepted 17 November 1997

coagulation, carrier protein synthesis and lipid metabolism. The liver also plays a significant role in glucogenolysis and gluconeogenesis, synthesis in the hepatocytes of very low density lipoproteins, and degradation of ammonia and its conversion to urea[19].

The hepatocyte phenotypically expresses more of the human genome than any other cell of the body by using virtually every enzyme, receptor and transport mechanism in the genetic code. The liver to date cannot be replaced by mechanical, physical or biochemical support that does not use viable hepatocytes. The anhepatic state is not compatible with life for extended periods; liver 'failure' and liver 'shock' are relative but overused terms describing compromise of any liver function. If the liver truly fails, death follows rapidly. However, the organ has the capability of regeneration, even after massive hepatic resection or after extensive injury[21].

Incidence, aetiology and associated injuries in liver trauma

Size and location make injury to the liver common: it occurs in 20, 30 and 40 per cent of patients operated on for blunt, gunshot and stab wounds respectively[20]. Overall, blunt injury, usually secondary to motor vehicle accidents, is the commonest cause. In a series of 136 patients reported by Croce *et al.*[5] in Memphis, Tennessee, 95 per cent of injuries were secondary to vehicle accidents, compared with 72 per cent of 404 patients in a multicentre review reported by Pachter and colleagues at New York University[22]. However, in another series of 1000 patients from Houston, Texas, Feliciano *et al.*[23] reported an incidence of 86 per cent of penetrating injuries, with only 14 per cent due to blunt trauma. A previous report from the same institution in 1976[24] described an incidence of 54, 31 and 15 per cent for gunshot wounds, stab wounds and blunt injuries respectively. In most parts of the USA and in Europe, however, such high numbers of penetrating injuries do not occur.

Injuries at other sites which are associated with penetrating trauma to the liver are common, occurring in up to 63 per cent of patients and mostly in the gastrointestinal tract[23]. After blunt hepatic injury, associated injuries are noted in 4–15 per cent of patients[25,26]. The association of diaphragmatic rupture with blunt hepatic injury has also been described, with an incidence of 3–9 per cent[25-28].

Current classification (Liver Organ Injury Scale)

Currently, hepatic injury is best described using the classification of the Organ Injury Scaling Committee of the American Association for the Surgery of Trauma (AAST). This was first outlined in 1989[29] and revised in 1994[30]. The advantage of this classification is the incorporation of both preoperative computed tomography (CT) and intraoperative assessment of extent of injury, including segmental anatomy (*Table 1*).

Diagnosis of liver injury

Peritoneal lavage

For the past quarter of a century, diagnostic peritoneal lavage has been used as the standard technique of choice for the diagnosis of acute intra-abdominal haemorrhage after blunt abdominal trauma[31,32]. It is fast, sensitive, accurate and relatively simple to perform. On the other hand, it is invasive, cannot diagnose retroperitoneal injury and is not a good predictor of therapeutic laparotomy. Non-selective exploratory laparotomy, performed on the basis of a positive lavage, results in a 3–25 per cent rate of non-therapeutic intervention[33], and some series have reported that half or more of hepatic injuries are not actively bleeding at the time of laparotomy[5,6,33].

Abdominal ultrasonography

Abdominal ultrasonography is accurate and useful in the evaluation of blunt abdominal trauma[34]. Most major trauma centres in the USA are moving towards the use of abdominal ultrasonography and CT as either an adjunct to or a replacement for lavage. In Europe and Japan, diagnostic abdominal ultrasonography has already replaced lavage as the diagnostic tool of choice[35,36].

Abdominal ultrasonography combines the advantages of lavage (fast and accurate) with those of CT (non-invasive and accurate). In a report by McKenney and associates[37] from the University of Miami, ultrasonography yielded a sensitivity of 88 per cent, a specificity of 99 per cent and an accuracy of 97 per cent in detecting intra-abdominal

Table 1 American Association for the Surgery of Trauma Organ Injury Scale: liver

Grade*		Description of injury†
I	Haematoma	Subcapsular, non-expanding, less than 10 per cent of surface area
	Laceration	Capsular tear, non-bleeding, less than 1 cm parenchymal depth
II	Haematoma	Subcapsular, non-expanding, 10–50 per cent of surface; or intraparenchymal, non-expanding, less than 2 cm in diameter
	Laceration	Capsular tear, active bleeding, 1–3 cm parenchymal depth, less than 10 cm in length
III	Haematoma	Subcapsular, greater than 50 per cent surface area or expanding; ruptured subcapsular haematoma with active bleeding; intraparenchymal haematoma greater than 2 cm or expanding
	Laceration	Greater than 3 cm parenchymal depth
IV	Haematoma	Ruptured intraparenchymal haematoma with active bleeding
	Laceration	Parenchymal disruption involving 25–50 per cent of hepatic lobe
V	Laceration	Parenchymal disruption involving more than 50 per cent of hepatic lobe
	Vascular	Juxtahepatic venous injuries (i.e. retrohepatic vena cava/major hepatic veins)
VI	Vascular	Hepatic avulsion

Reproduced from Moore *et al.*[30] with permission. *Advance one grade for multiple injuries to the same organ. †Based on most accurate assessment at autopsy, laparotomy or radiological study injury in 1000 patients. Despite its advantages, ultrasonography lacks organ specificity and it is operator dependent. At present, the authors believe that for haemodynamically unstable patients, ultrasonography is a good initial screening test after blunt abdominal trauma to document whether or not there is a large haemoperitoneum present.

Abdominal computed tomography

The single greatest factor permitting safe non-operative management of hepatic injury after blunt trauma is CT. However, it is haemodynamic stability and not the appearance of the liver on CT scans that determines which patients should be considered for observation alone. Many of the initial fears about non-operative treatment of stable patients have been alleviated by the recognition that CT can accurately delineate the anatomy of the injury, while providing crucial information about the amount of haemoperitoneum and the presence of associated intra-abdominal injuries. In this institution, after initial resuscitation, patients are given 25 ml MD-Gastroview (ditrizoate meglumine; Mallinckrodt Medical, St Louis, Missouri, USA) in 725 ml water by mouth or nasogastric tube. In addition, all patients receive 2 ml/kg ioversol (Optiray; Mallinckrodt Medical) intravenously. Rapid axial scans are performed on a GE HiSpeed Advantage Helical Scanner (General Electric, Milwaukee, Wisconsin, USA). Without optimal imaging by CT, safe non-operative management of blunt hepatic injury would not be possible. The role of CT continues to expand as technology advances and some reports have documented its potential role in penetrating injury of the right thoracoabdominal region in haemodynamically stable patients[38,39].

Laparoscopy

Diagnostic laparoscopy has been used successfully in penetrating trauma[40], but its place in blunt abdominal trauma is not well defined. It currently plays no significant role in the staging of blunt liver injury, although in therapeutic mode it can be useful for draining a retained haemoperitoneum or perihepatic collections after the non-operative treatment of severe liver injury.

Non-operative management of liver injury

Historically, operation has been the generally accepted method of treating blunt hepatic injury. At the time of surgical exploration, however, the injury is frequently found to be minor. No evidence of active haemorrhage is found in 50–80 per cent of patients[5,6,33] and the rate of non-therapeutic laparotomy in this group of patients may be as high as 67 per cent[6]. These two findings set the stage for an overall reassessment of the management of blunt hepatic trauma. Non-operative management has been the standard method of care of paediatric patients for the past 20 years, with a success rate of around 90 per cent[41–43]. Currently, in the adult population, non-operative management of blunt hepatic injury ranges from 50 to 82 per cent of all such injuries reported[6]. In a multicentre report of 404 patients, the incidence of non-operative treatment varied from a low of 20 per cent to a high of 70 per cent, with a mean of 47 per cent[22].

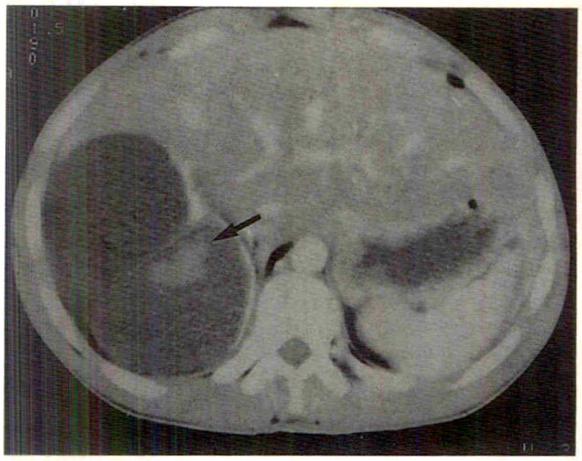

Fig. 1 Abdominal computed tomography demonstrating a large subcapsular haematoma and pooling of contrast agent (arrow), an indication of active intrahepatic haemorrhage

Criteria for non-operative management

Patients who are haemodynamically stable and who have no indications for laparotomy are ideal candidates for evaluation by emergency abdominal CT. In this select group, criteria for non-operative management include: (1) simple hepatic parenchymal laceration of intrahepatic haematoma, (2) absence of active haemorrhage (*Fig. 1*), (3) haemoperitoneum of less than 500 ml, (4) limited need for liver-related blood transfusions, (5) absence of diffuse peritoneal signs in patients not neurologically impaired, and (6) absence of other peritoneal injuries that would otherwise require an operation[21,44]. As previously noted, the results of conservative management of patients who meet these criteria have been excellent. As confidence has been gained with this management, the authors (and others) have expanded the acceptable volume of haemoperitoneum to 500 ml in haemodynamically stable patients[45]. More recently, Feliciano[46] has proposed non-operative management for any hepatic injury, regardless of its magnitude, if the patient is haemodynamically stable. This policy has been followed in a few strictly selected patients (*Fig. 2a*).

Failure of conservative treatment leads to surgery. An operation is required in patients who continue to need blood transfusion or whose vital signs deteriorate. Infection within the liver injury may also need a surgical solution. While increasing peritoneal signs and tenderness may be misleading, persistent or increasing abdominal pain should be treated with great caution.

Abdominal computed tomography follow-up

In complex hepatic injury, further evaluation with abdominal CT may by useful to document continuing haemorrhage which may cause otherwise unexplained blood losses, to document healing in extensive injury (*Fig. 2b*), and to evaluate the presence of intrahepatic or perihepatic fluid collections that may required percutaneous or laparoscopic drainage. Abdominal CT for documentation of liver wound healing before discharge from hospital, although desirable, is used inconsistently. In the multicentre review of 404 patients by Pachter *et al.*[22], 198 (49 per cent) underwent follow-up CT after the initial study; the timing of the repeat scan varied from 1 to 238 days. Of these 198 patients, 52 (26 per cent) underwent repeat scanning from 1 to 6 days after injury. Of these 52, only five showed any degree of resolution of the injury. Eighty-nine patients (45 per cent) underwent subsequent scanning from day 7 to day 10. Of these 89 patients, 69 (78 per cent) were noted to have had improvement of the original injury. Some of the authors of this multicentre review considered that, when injuries are not extensive (grades I–III), follow-up CT studies are superfluous. In another retrospective review of patients managed without operation, no statistically significant difference in outcome was found in patients with grade III or lower hepatic injury between one scan and more than one scan[47]. In this institution at present routine CT follow-up is individualized and not obtained routinely.

Relationship of computed tomography scan, organ injury and non-operative management

Conservative management of liver injury was described initially for grades I–III[22]. Currently, clinical experience shows that some haemodynamically stable patients with complex hepatic injuries (grades IV and V) may be safely managed without operation (*Fig. 2a*)[1,5,22,46,48]. However, in the multicentre review of 404 patients[22], 67 per cent who required an operation after failure of non-operative management were patients with grade IV or grade V injury. These are the patients who benefit from being closely observed in an intensive care environment. It is both the authors' experience and current clinical consensus that it is haemodynamic stability, rather than the extent of liver injury, that should determine whether or not a patient is managed without operation.

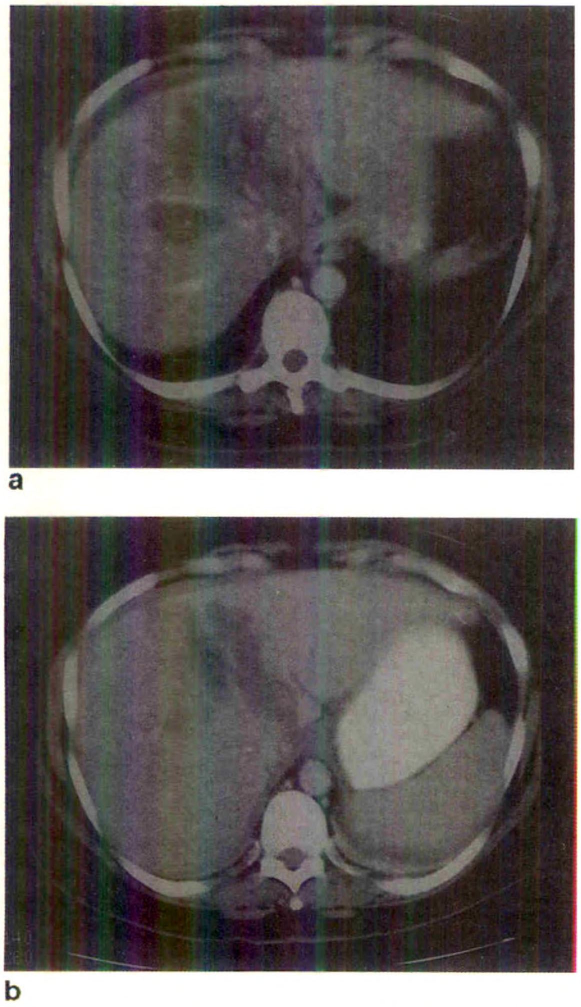

Fig. 2 a Extensive liver laceration (grade V) with no significant haemoperitoneum managed conservatively with no complications. b Follow-up computed tomography shows partial resolution of the haematoma and hepatic healing 7 days after the original injury

Resumption of normal activities

One of the most controversial issues regarding the non-operative management of hepatic injury is what constitutes an appropriate interval of time between the injury and resumption of normal activities, to avoid delayed haemorrhage. From a speculative standpoint, most clinicians have suggested that physical activities be limited and contact sports avoided for 3–6 months.

Two reports have indicated, however, that this time is probably too long. Karp *et al.*[41] documented almost complete liver restoration after 3–4 months. More recently, Dulchavsky *et al.*[49] demonstrated in an experimental model that, after 3–6 weeks, the wound-breaking strength of a hepatic injury equals that of uninjured liver. Their recommendation was that 'fear of reinjuring the liver injury allowed to heal by secondary intent should not limit the return of post-discharge activity beyond the normal restrictions recommended after any laparotomy'. It is known that a hepatic injury followed by serial CT shows healing by 3–4 months[45,50]. This may greatly underestimate wound-breaking strength and delaying return to full activity beyond this time seems unwarranted[1,22]. Currently, the authors advise patients to avoid contact sports or heavy physical activity for only 8 weeks after liver injury of grades III–VI.

Role of interventional radiology in blunt liver injury

Interventional radiology can be extremely useful: (1) to document active haemorrhage in subcapsular haematomas, (2) as a salvage alternative to surgery in the face of continuous haemorrhage in patients who remain haemodynamically stable, (3) in the diagnosis and treatment of haemobilia (*Fig. 3*), and (4) in the treatment of retained collections or perihepatic sepsis (using percutaneous techniques). Arteriography is useful in selected patients after operative perihepatic packing who have postoperative evidence of ongoing haemorrhage. Biliary endoscopy may be helpful in the diagnosis and treatment of complications secondary to complex liver injury[16,18].

Morbidity and death

Missed injuries

A major concern when treating hepatic trauma without operation is that of missing an injury. Some controversy originates from confusion between associated injury and a truly missed injury. The incidence of associated abdominal injury after blunt hepatic trauma in patients managed without operation ranges from 13 per cent[50] to 35 per cent[45]. However, the incidence of truly missed intra-abdominal injury ranges from 0·5 per cent[22] to 12 per cent[45] when abdominal CT is used, and from 5 to 15 per cent when CT is not performed[25,26]. In a review of 899

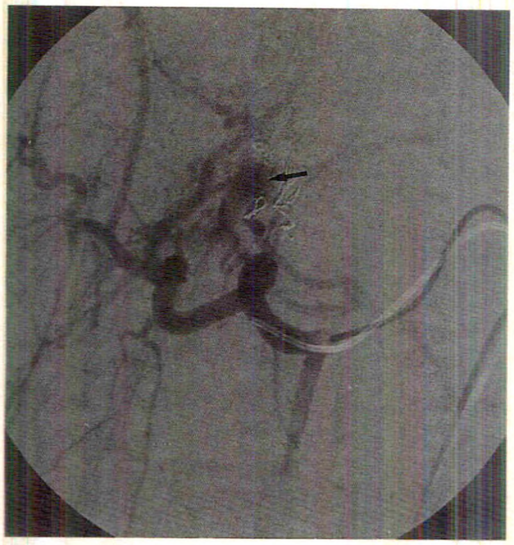

Fig. 3 Patient with haemobilia from a traumatic liver lesion (arrow) treated with embolization

patients, when strict guidelines for conservative management were followed and CT was used routinely, the incidence of missed injury was 0·2 per cent (two enteric injuries)[6]. It has also been reported that the most common cause of missed injury is wrong interpretation and poor quality of the initial scan. In their review of complex hepatic injuries, Pachter and Feliciano[6] emphasize that 'despite an accuracy rate of 97 to 99 per cent in detecting associated intraabdominal injuries, the CT scan is not infallible. Also it does not serve as a substitute for constant re-examination, preferably by the same set of examiners, of the patient whose abdominal examination remains equivocal in spite of a CT scan'. In patients for whom non-operative treatment of hepatic injury is chosen, the authors' current policy is to have a radiologist and the attending trauma surgeon read the initial CT scan, which must be of excellent quality, and all patients are admitted for observation under the care of the trauma service.

Delayed haemorrhage

Delayed hemorrhage is the most common complication of the non-operative management of hepatic injury and it is the usual indication for a delayed operation. In selected series, where strict guidelines for non-operative management were followed, the incidence of delayed haemorrhage ranged from 0 per cent[45,51,52] to less than 3·5 per cent[22,50], and blood transfusions were required in fewer than 20 per cent of those patients, with most requiring less than 4 units of blood[22,45,50–52].

Common treatment errors in patients with delayed haemorrhage are: (1) assuming that the haemorrhage is not related to the liver, (2) treating ongoing liver haemorrhage with multiple (more than four) blood transfusions in the hope that it will stop, (3) misreading the abdominal CT scan and underestimating the amount of haemoperitoneum or active hepatic haemorrhage (contrast 'pooling'), and (4) overestimating the amount of blood loss from associated injuries. The protocol in this trauma service for suspected haemorrhage in patients managed without operation indicates an immediate laparotomy or abdominal CT, depending on the haemodynamic stability of the patient (*Fig. 4*).

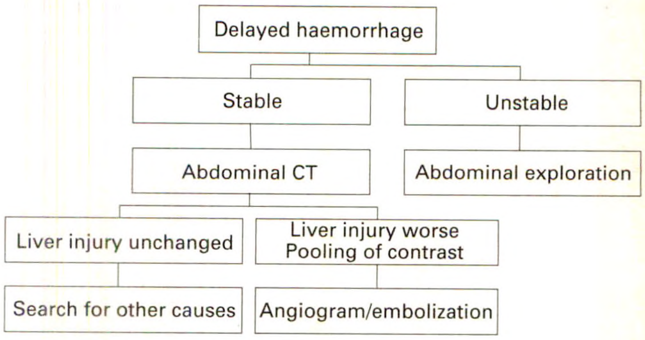

Fig. 4 Algorithm for management of delayed haemorrhage following blunt liver injury. CT, computed tomography

Biliary fistula and liver abscess

The incidence of biliary fistula in patients treated without operation after blunt hepatic injury ranges from 0·5 per cent[25,45] to 20 per cent[12]. This range is more a reflection of the methods used for diagnosis than of the true incidence. Available information indicates that most of these perihepatic collections are currently managed expectantly or by interventional radiologists using percutaneous techniques, with a success rate close to 70 per cent[22,45]. Patients with a well organized intrahepatic abscess may undergo a trial of medical treatment, with attempted percutaneous drainage. If there are no signs of improvement, or if fungi are isolated from the blood or the abscess site, more aggressive surgical treatment should be considered.

Haemobilia and bilhaemia

Intrahepatic artery pseudoaneurysm formation with haemobilia, classically described by Sandblom[53] as 'haemorrhage into the biliary tract', occurs when an injury or disease causes communication between the biliary tract and blood vessels. A history of abdominal trauma, jaundice, right upper quadrant colicky pain and blood in either vomitus or stool should point to this diagnosis. Iatrogenic causes are now most commonly encountered, as a result of percutaneous diagnostic and therapeutic procedures performed in the hepatobiliary system[54,55]. The management of haemobilia has evolved with the capabilities of interventional radiology. Once a pure surgical condition (including selective hepatic artery ligation and/or hepatectomy), haemobilia is now more often managed by percutaneous selective hepatic artery embolization (*Fig. 3*), with surgery reserved only for patients in whom such treatment fails[54,55], or for those with large intrahepatic cavities and/or sepsis[55,56]. When a surgical option is considered, vascular control should be obtained either by preoperative embolization or during surgery to avoid catastrophic haemorrhage. The incidence of haemobilia after conservative management of blunt hepatic injury is about 1 per cent[55] with most cases being secondary to blunt liver trauma[54,55].

Bilhaemia is an extremely rare complication of severe deceleration injury to the liver, in which the hepatic venules and the intrahepatic bile ducts rupture. This is followed by the formation of an extensive liver haematoma within necrotic tissue, leading to excessive serum bilirubin levels with only moderately raised levels of liver enzymes secondary to a traumatic intrahepatic biliovenous fistula. Progressive reabsorption of the cavity occurs in the ensuing days, with passage of bile from the disrupted bile ducts to the intrahepatic veins by a difference in gradient pressure of 15–20 cmH$_2$0 between the two systems (*Fig. 5a*). The ideal treatment of post-traumatic bilhaemia is by endoscopic sphincterotomy and biliary endostenting (*Fig. 5b*)[18]. Most current experience comes from Europe[57–59].

Extrahepatic bile duct stricture

Since more patients with complex hepatic injuries are being successfully treated conservatively and surviving[22], an increase in the number and complexity of complications secondary to non-operative management is likely. Recent reports[16,60–62] suggest that the incidence of biliary ductal disruption or intrahepatic ductal stenosis secondary to spontaneous healing of a severe liver injury is probably higher than has been appreciated previously. It is suspected that the risks of intrahepatic bile duct stenosis are even higher after extensive liver embolization to control haemorrhage in complex injuries. Because of the lack of experience with this uncommon condition, there is no uniformity of treatment criteria. Based on a limited experience with this rather uncommon complication[16], the authors believe that a conservative approach is warranted initially, leaving any surgical option as a late alternative.

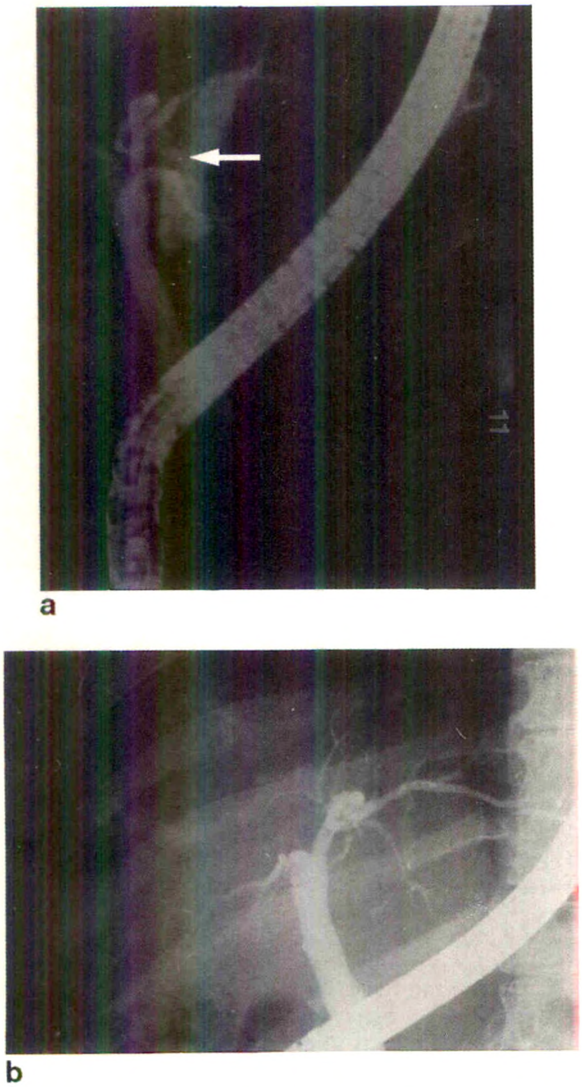

Fig. 5 Post-traumatic bilhaemia. **a** There is communication between the bile ducts and the hepatic veins (arrow). **b** Successful treatment with endoscopic biliary endostenting and sphincterotomy

Mortality rate

The overall mortality rate after blunt injury to the liver remains at 7–13 per cent, with most deaths resulting from associated injuries. The mortality rate arising from the liver injury itself is from 0 to 0·4 per cent in recent reports[5,22,45,63].

Future of non-operative treatment of liver injury

In 1908 Pringle[64] made the following observations: (1) bleeding from a significant liver laceration would not stop, (2) the liver would not heal, and (3) surgical intervention would be the only way to treat any liver injury. Based on these premises, hepatic injury has been managed surgically for the past eight decades. In the early 1970s, Richie and Fonkalsrud[65] and Popovsky and associates[66] reported the first successful non-operative treatment of liver injury. However, major changes in the conservative approach to hepatic injury started only in the early 1980s, with the report by Karp and associates[41] of non-operative management of hepatic injuries in 17 children. They hypothesized that liver repair proceeds in four stages: (1) resorption of blood, (2) coalescence of the laceration, (3) decrease in the size of the defect, and (4) restoration of liver homogeneity after 3–4 months. In the light of such observations and encouraging reports from many major trauma centres in the USA[5,22,44–46] and Europe[48,67,68], non-operative management of blunt hepatic injury in adults has increased dramatically in the past 10 years (*Table 2*). It is not now uncommon to read reports describing successful conservative management of blunt hepatic trauma in over 85 per cent of cases, and this is expected to be consistently over 90 per cent in the near future[4,22]. Nine of the authors' most recent ten patients with severe liver injury (grades IV and V) were successfully treated

Table 2 Evolution of non-operative management of adult hepatic trauma

Year	No. of patients	Hospital stay (days)	Transfusion (units)*	Success rate (%)
1988	20	13·3	4·0	90
1989	31	16·6	4·0	100
1990	84	11·5	2·0	95
1991	55	13·0	1·0	96
1992	93	13·9	1·3	95
1993	64	n.a.	n.a.	84
1994	148	16·2	1·6	95
1997	14	n.a.	n.a.	86

Data compiled from Pachter and Hofstetter[4], Farnell *et al.*[69], Mirvis *et al.*[33], Hiatt *et al.*[70], Frederico *et al.*[52], Knudson *et al.*[71], Pachter *et al.*[7], Durham *et al.*[45], Bynoe *et al.*[72], Hollands and Little[73], Hammond *et al.*[51], Sugimoto *et al.*[60], Boone *et al.*[74], Sherman *et al.*[50], Meredith *et al.*[1], Allins *et al.*[75]. n.a., Data not available. *A unit of transfusion is approximately 250 ml of blood without operation, with most patients requiring less than 500 ml of blood and staying in hospital for fewer than 10 days. On the other hand, it is important to emphasize that these results cannot be obtained unless the following criteria are met: (1) haemodynamic stability, (2) absence of peritoneal signs or localized only in the right upper quadrant, (3) a technically flawless CT scan with documentation of hepatic injury, (4) absence of other intra-abdominal injuries in the abdominal CT scan, and (5) no more than four liver-related blood transfusions. If any one of these criteria is not met, alternative measures should be considered immediately (*Fig. 4*). Neurological integrity has been mentioned as a requirement for the safe non-surgical management of blunt liver injury. The authors believe that, by itself, neurological integrity need not be an absolute requirement for conservative treatment as long as the patient is haemodynamically stable.

Conclusion

In haemodynamically stable patients with blunt hepatic injury, an expeditious abdominal CT scan and a proper classification using the AAST Organ Injury Scale[30] will facilitate non-operative management and the development of protocols. Based on this contemporary review and personal experience, the authors' current treatment philosophy in patients with blunt hepatic trauma includes the following tenets: (1) haemodynamic stability rather than findings on CT determines which patients should be managed conservatively, (2) in haemodynamically stable patients less treatment is probably the best treatment, (3) most blunt hepatic injuries can be managed without operation with minimal morbidity and mortality rates, (4) increasing transfusion requirements should be regarded with suspicion, (5) the interventional radiologist should be part of the treatment team, (6) when conservative management fails, abbreviated laparotomy and planned reoperation should be considered at an early point during surgery, and (7) most complications should be managed in a non-operative fashion unless clear surgical indications are present.

Review

Early colorectal cancer: recognition, classification and treatment

K. S. MAINPRIZE, N. J. McC. MORTENSEN and B. F. WARREN*

Background With the introduction of colorectal cancer screening and improvements in endoscopic technology, the recognition and management of early colorectal cancer assumes increasing importance.

Methods A literature review was undertaken using Medline (National Library of Medicine, Washington DC, USA) searches of the headings early colonic, colorectal and rectal cancer, carcinoma and adenocarcinoma up to and including 1997. All relevant references were examined.

Results and conclusion The diagnosis, classification and treatment options are described. Accurate diagnosis, preoperative and histopathological staging is crucial in the management of early colorectal cancer.

Some 10 per cent of all patients with colorectal cancer have Dukes A tumours[1] and, although about 90 per cent will be cured by surgery, 10–20 per cent go on to develop recurrent disease[2,3]. As the operative mortality rate for elective surgery of this disease is less than 10 per cent and adjuvant treatment is yet to have a substantial impact, early diagnosis offers the only hope at present for improved survival.

The number of early colorectal cancers discovered will increase as screening is introduced; the proportion of Dukes A colorectal cancers may rise to 53 per cent[4]. Two recently published randomized controlled trials of faecal occult blood screening reported increased proportions of Dukes A tumours to 22 per cent[5] and 20 per cent[6]. In a recent Japanese study 75 per cent of asymptomatic cancers were T_{is} (this term, which is not used in Europe, is discussed below) and 22 per cent were T_1 (*Table 1*)[7]. Early colorectal cancer is defined as invasive tumour limited to the mucosa or submucosa. While this can be classified as Dukes stage A, this Dukes category also includes all tumours confined to the bowel wall; to provide better information on the pattern and prognosis of the disease a number of newer staging methods and systems have been developed. Many have been introduced in Japan and are either not known or neglected in European studies. A better definition of local invasion and the probability of lymph node metastasis is essential for the proper use of curative local excision techniques.

Table 1 Tumour staging of colorectal cancer using the tumour node metastasis staging system[14]

Stage	Description
T_X	Primary tumour cannot be assessed
T_0	No evidence of primary tumour
T_{is}	Carcinoma *in situ*: intraepithelial or invasion of the lamina propria
T_1	Tumour invades the submucosa
T_2	Tumour invades the muscularis propria
T_3	Tumour invades through the muscularis propria into the subserosa, or into the non-peritonealized pericolic or perirectal tissues
T_4	Tumour directly invades other organs or structures and/or perforates the visceral peritoneum

T, tumour

Macroscopic classifications

Morphology

Early colorectal cancer presents in many forms and a macroscopic classification has been proposed which is similar to that for early gastric cancer (*Fig. 1*)[8]. The highest proportion of lesions occurs in the rectum and the lowest in the right colon[9,10], but this may reflect the increased use of flexible sigmoidoscopy in Japanese screening programmes[10].

Polyps have been divided into sessile and pedunculated according to their shape, with 42–85 per cent of early colorectal cancers pedunculated and 15–58 per cent sessile[8,10,11]. Patients with pedunculated polyps are less likely to have invasion into the deep submucosal layer[10] (see below). Maruyama classified lesions in the colon according to morphology[13], sessile or polypoid, and according to the length of stalk (*Table 2*); this has been developed further and related to the type of tumour likely to be found within the lesion (*Table 3*)[13]. All lesions of 6–15 mm in diameter fall into the following four types (a–d). For lesions of 6–9 mm in diameter, type a (long stalk) occur mostly in the right colon, type b (short stalk or sessile) have no anatomical predilection, type c (plaque-like) occur in the proximal and descending colon in 30 per cent of cases, and type d (central depression) are all malignant.

Microscopic classifications

The depth of invasion of colorectal cancers has been staged using Dukes classification since 1932. More recently the tumour node metastasis (TNM) classification has become increasingly popular (*Table 1*)[14].

Paper accepted 20 October 1997

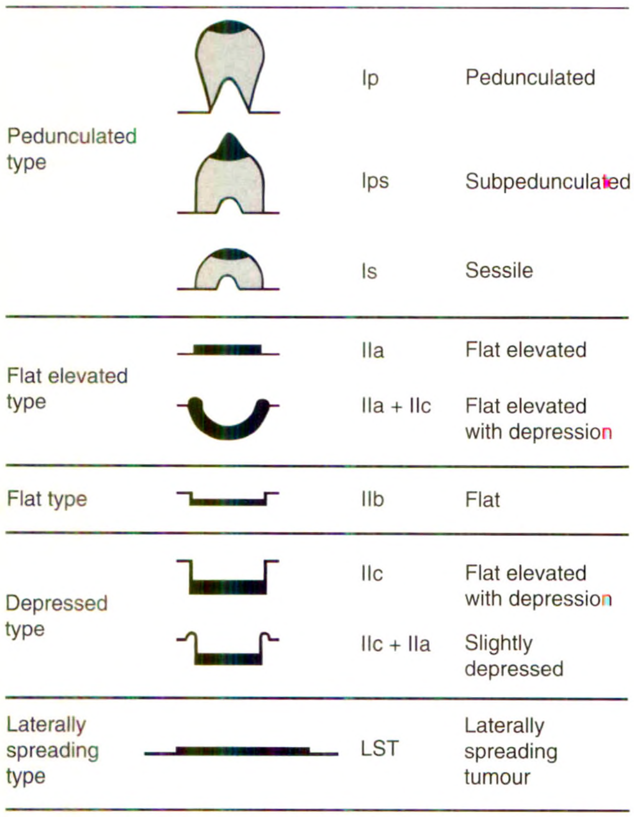

Fig. 1 Macroscopic classification of early colorectal cancer according to Kudo[30]

Table 2 Maruyama classification of the morphology of colorectal lesions[13]

Type	Description
a	Lesion with a long stalk
b	Lesion with a short stalk or a sessile lesion
c	Plaque-like lesion
d	Lesion with a central depression
e	Other

Table 3 Likelihood of cancer within each Maruyama group[13]

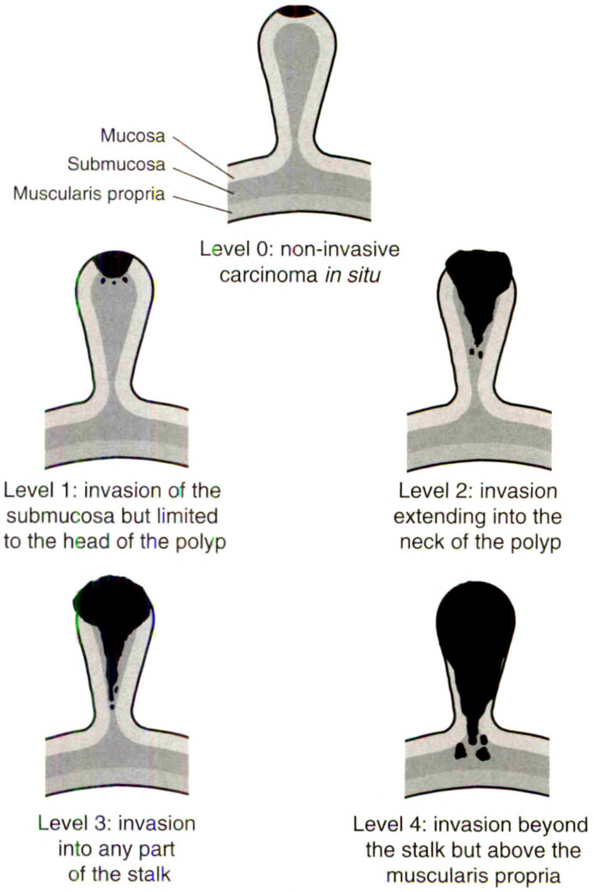
Type	Description
a	Benign or early colorectal cancer
b or c greater than 1 cm in diameter with indentation of the colonic wall	Great probability of being early colorectal carcinoma
d with slight depression	Benign or early colorectal cancer
d with severe depression	Benign or early colorectal cancer
e	Mostly villous tumours

Mucosal carcinoma

Europeans are reluctant to use the term carcinoma *in situ* and do not accept intramucosal carcinoma. The Japanese, however, have studied the pattern of growth of colorectal cancer within the mucosa and have subdivided it into intramucosal polypoid growth and intramucosal non-polypoid growth[15]. In one group of 337 polyps, 98 (29 per cent) were early colorectal cancers of which 81 were described as mucosal and 17 as submucosal[16]. While molecular biological techniques may help to identify the earliest stages of malignant transformation from severe dysplasia, at present there is insufficient evidence to support the use of the term 'intramucosal carcinoma'.

Submucosal invasion

Submucosal invasion was described by Haggitt and colleagues[17], who classified early colorectal polyp cancers into pedunculated and sessile types (*Fig. 2*). While this classification has been used widely to assess adequacy of excision in colonoscopic polypectomy specimens, it is less useful for flat lesions without a stalk. The Japanese have several classifications for invasion of the submucosa, including both vertical invasion and horizontal invasion (*Tables 4* and *5*)[10,17], which can be applied more readily to large flat lesions. The former divides the submucosa into upper (Sm1), middle (Sm2) and lower (Sm3) thirds, with some groups attempting to apply measurements within the divisions into thirds[10]. This divides the upper Sm1 layer horizontally according to the thickness of the invasive component of the tumour (*Fig. 3*). In patients with pedunculated polyps, Sm1 is similar to Haggitt level 1, Sm2 is similar to levels 2 and 3, and Sm3 is similar to level 4[10] (*Figs 2* and *3*).



Mucosa
Submucosa
Muscularis propria
Level 0: non-invasive carcinoma *in situ*
Level 1: invasion of the submucosa but limited to the head of the polyp
Level 2: invasion extending into the neck of the polyp
Level 3: invasion into any part of the stalk
Level 4: invasion beyond the stalk but above the muscularis propria

Fig. 2 Classification of early colorectal cancer in polyps according to Haggitt *et al.*[17]

Table 4 Vertical invasion of the submucosa[3]

Class	Description	Kikuchi definition
Sm1	Infiltration into the upper third of the submucosal layer	Invasion from the muscularis mucosa to a depth of 200–300 μm
Sm2	Infiltration into the middle third of the submucosal layer	Intermediate invasion
Sm3	Infiltration into the lower third of the submucosal layer	Invasion near the inner surface of the muscularis propria

Table 5 Horizontal invasion of the upper third of the submucosa (Sm1)

Class	Description
Sm1a	Horizontal invasion limited to less than one-quarter of the width of the tumoral component in the mucosa
Sm1b	Horizontal invasion limited to one-quarter to one-half of the width of the tumoral component in the mucosa
Sm1c	Horizontal invasion greater than one-half of the width of the tumoral component in the mucosa

Adenoma and early colorectal cancer

Early colorectal cancer seems to have two patterns of progression: relatively slow development of cancer in an adenoma, as demonstrated by the adenoma eventually becoming cancerous[18], and a more controversial rapid deep cancerous invasion, as demonstrated by minute flat lesions (type IIb or IIa) arising *de novo*. The proportion of cancers with persisting adenoma decreases with increasing invasion: 74 per cent in mucosal cancer, 33 per cent in submucosal cancer and 0 per cent in cancer with invasion to the proper muscle layer (muscularis propria)[19]. The 'flat' adenomas are more likely to be present with adenoma[12]. It has therefore been proposed that early colorectal cancer loses a component of adenoma in the process of developing into a cancer as it invades the proper muscle layer.

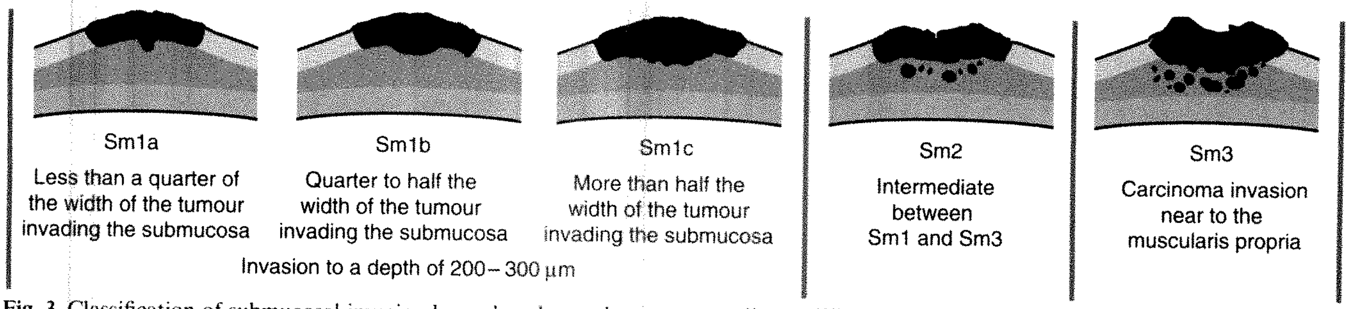
In a study of over 5000 adenomas resected from 24 patients with familial adenomatous polyposis, 18·3 per cent were flat, 12 per cent depressed and 69·7 per cent polypoid[20]. Flat adenomas (types IIb and IIc) were first described by Muto *et al.*[21] and are said to have an overall malignancy rate higher than that of small polypoid adenomas[22–24]. There is no relationship between site and malignancy, but flat adenomas are situated more proximally than 'ordinary' ones[21,23]. The presence of a central depression in a flat adenoma is a sign of increased dysplasia[22,25,26] and it has been suggested that this may be used to determine the degree of malignancy of a lesion at endoscopy. Early cancers with high malignant potential have a slight depression associated with redness on the mucosal surface; carcinomas with high malignant potential have a superficial, minute, irregularly grooved structure or irregular shape with a slight depression on the mucosal surface[27]. The above notwithstanding, flat adenomas may not be precursors of cancer[28].

Diagnosis of early colorectal carcinoma

Detection of flat and depressed types of early colorectal carcinoma during colonoscopy requires awareness of the various macroscopic appearances (*Fig. 1*) and of the fact that there is no elevation above the mucosal surface to facilitate the diagnosis. The incidence of submucosal cancer is higher in early colorectal cancer with depression (IIc, IIc + IIa and IIa + IIc) than in that without depression or in the elevated type (Ip, Isp and Is)[29]. Superficial granularity and nodularity on elevated lesions assists in making the diagnosis of submucosal invasion, and these features on the depressed area of the lesion also suggest submucosal invasion (*Table 6*). Early colorectal cancer is easily overlooked at endoscopy and clues to detection include any irregularity of the mucosal surface, such as pinkishness of the mucosa, fading of the mucosal colour, minute depressions and/or haemorrhagic spots. If an irregularity is observed, dye spraying may make the lesion easier to visualize[30], revealing the innominate (fine) grooves that run circumferentially around the normal colonic surface[31] (some have likened these to the gyri of the brain). These grooves disappear in neoplastic lesions, but remain visible in non-neoplastic lesions and in normal colonic mucosa[32,33].

Another helpful technique is air transformation. When air is insufflated and the colon is observed during distension, the discovery of flat and depressed types is made easier. The depressed part may be emphasized by decreasing the air pressure, as the margins become elevated and the central excavation becomes more prominent; with maximal distension the lesion becomes flat[30].

Magnifying fibre-colonoscopy and dissecting microscopy[34] have been used to study pit patterns in the colon, and modern developments in fibreoptics now allow 100 times magnification *in vivo* during conventional colonoscopy[35]. In the normal and abnormal colorectal



Sm1a
Less than a quarter of the width of the tumour invading the submucosa

Sm1b
Quarter to half the width of the tumour invading the submucosa

Sm1c
More than half the width of the tumour invading the submucosa

Invasion to a depth of 200–300 μm

Sm2
Intermediate between Sm1 and Sm3

Sm3
Carcinoma invasion near to the muscularis propria

Fig. 3 Classification of submucosal invasion by early colorectal cancer according to Kikuchi *et al.*[10]

Table 6 Endoscopic features suggesting submucosal invasion

Depression
Superficial granularity and nodularity
Irregularity of mucosal surface
Fading of mucosal colour
Haemorrhagic spots

Type	Pit pattern	Definition	Usual histopathological findings
Type I		Round pits	Normal
Type II		Asteroid or papillary pits	Hyperplastic
Type IIIs		Small tubular	Intramucosa adenocarcinoma or depressed adenoma
Type III1		Large tubular or roundish pits	Protruded adenoma
Type IV		Branch or gyrus-like pits	Adenoma or intramuscular adenocarcinoma
Type V		Non-structured pits	Submucosal adenocarcinoma

Fig. 4 Classification of the pit pattern in the colorectal mucosa[30]

mucosa there are five types of pit pattern (*Fig. 4*) which may assist in the diagnosis of early colorectal cancer, as types IIIs and V are found in flat and depressed lesions. Pit patterns have been shown to correspond well with histopathological findings[30].

Use of the high-resolution colonoscope in conjunction with indigo carmine dye has helped in the diagnosis of diminutive colorectal polyps by further aiding the study of pit patterns. Hyperplastic polyps have a characteristic pit pattern of orderly arranged 'dots', resembling normal mucosa, whereas adenomatous polyps have innominate grooves. It has been claimed that the sensitivity and specificity of this technique in distinguishing adenomatous from non-adenomatous colorectal polyps are 93 and 95 per cent respectively[36].

The endoscopic findings associated with adenoma and sessile early colorectal cancer with submucosal involvement are distinguishable by the loss of symmetry, depression or flat surface[37]. One study assessed the diagnostic criteria for early colorectal cancer and compared the radiographic and endoscopic diagnosis based on 157 foci of early cancer[38]. Early cancers were missed by both methods, but radiography missed almost twice as many cancers as endoscopy. It was proposed that both examinations should be carried out if at all possible and that endoscopy should precede radiology to reduce the number of radiologically missed lesions to a minimum. Using such guidelines, 91 per cent of sessile early colorectal cancers may be detected.

Lymph node metastasis and early colorectal cancer

The incidence of lymph node metastasis varies from 0 to 15·4 per cent in early colorectal cancer[10,11,39–49]. The presence of lymph node metastases cannot be determined accurately without colectomy, but several groups have tried to define the risk factors for such metastasis (*Table 7*). The size of the tumour may not be relevant[10,11], but this is disputed by some[50]. Features that may be associated with the presence of lymph node metastasis include 'tumour budding', in which small clusters of undifferentiated cancer cells occur ahead of the invasive front of the lesion[52], the pattern of cancer growth in the submucosal invasive front, tumour differentiation at the leading edge of the lesion, sessile configuration of the lesion, location of the cancer in the rectum[10], and cancer cells in the lymphatics and vessels[16,44,53]. The Japanese Research Society for Cancer of the Colon and Rectum has classified the degree of lymphovascular invasion: ly0 or v0 represents respectively no lymphatic or no vascular invasion, ly1 or v1 signifies very slight invasion, ly2 or v2 denotes moderate invasion, and ly3 or v3 indicates massive invasion[54].

Hase and colleagues[12] examined five histological risk factors for lymph node metastasis in early colorectal cancer (*Table 8*) and found that patients with fewer than four risk factors had no nodal metastases, whereas those with four or five factors had nodal metastasis rates of 33·3 and 66·7 per cent respectively. Occasionally only the deepest part of the tumour contains nests of anaplastic cells that invade the fibrous tissue or vasculature. This focally undifferentiated component probably plays a role

Table 7 Histopathological features and risk of lymph node metastasis[41]

Low risk	High risk
Adenocarcinoma and mucinous adenocarcinoma, well or moderately differentiated	Poorly differentiated adenocarcinoma and mucinous adenocarcinoma
	Signet-ring cell carcinoma
	Undifferentiated carcinoma
	Adenocarcinoma, well or moderately differentiated, containing a focus of any of the above
	Vascular invasion (lymphatic or venous)
	Carcinoma at the resection margins

in the biological evolution of the lesion. One review of the literature in 1989 noted that all patients with lymph node or distant metastases had poorly differentiated carcinomas or tumours with a focus of poorly differentiated carcinoma[41]. It seems important, therefore, for the histopathologist to identify any anaplastic component in an early colorectal cancer as this correlates with the risk of lymph node metastasis.

Considering the intramucosal carcinoma recognized by the Japanese, of 132 patients studied by one group 86·4 per cent had the polypoid growth type, which carried a low incidence (10·2 per cent) of submucosal invasion and minute or scattered invasion into the submucosa. Of the 13·6 per cent of adenocarcinomas that were of the non-polypoid growth type, all had massive invasion with a high frequency of submucosal intralymphatic and venous invasion (72·2 per cent). Non-polypoid growth was not found to be associated with adenoma and so the authors postulated that this type of lesion probably developed *de novo* into the so-called cancer. Interestingly, all of their cases of advanced colorectal cancer were of the non-polypoid type[14].

Lymph nodes containing tumour from early colorectal cancer may well be small, 2–6 mm in diameter in 50 per cent of positive lymph nodes in one series[55]. Others have found that the proportion of positive lymph nodes increases with increasing size of the tumour[50]. Approximately half the patients with lymph node metastases from early colorectal cancer have foci of poorly differentiated tumour, and lymphatic invasion is present in about one-quarter. Distant metastases to the liver and lung have been found with early invasive colorectal cancer, but all have been associated with a primary tumour in the rectum, a sessile type configuration, Sm3 level of invasion and positive lymphatic invasion.

Recurrence of early colorectal cancer

The recurrence rate of early colorectal cancer is between 6·3 and 8·9 per cent[11], but in the presence of lymph node metastases this increases to 36·4 per cent[11,39,44]. The recurrence rate also depends on the type of initial resection performed and this is discussed below.

Treatment

The treatment of flat or depressed types of early colorectal cancer has until recently consisted of either endoscopic removal or surgery. Endoscopic removal includes standard and advanced polypectomy (the injection submucosally of a saline cushion before snaring[56]) which are suitable for small cancers, particularly those that are pedunculated, with further treatment depending on histological findings. Lesions less than 3 cm in diameter should be resected by advanced polypectomy, which can be considered as definitive treatment for intramucosal cancer.

Table 8 Histological risk factors for lymph node metastasis according to Hase *et al.*[12]

Tumour budding
Poor demarcation of cancer at the invasive front
Moderately and poorly differentiated tumour in the submucosal invasive front
Increasing depth of submucosal invasion
Lymphatic invasion

Lesions with discrete infiltration of the submucosa (Sm1a and Sm1b without vessel invasion) may also be suitable for advanced polypectomy. Sm1b with vessel invasion and beyond carries an increased risk of lymph node metastasis and so classical surgical treatment (such as anterior resection) is necessary. Spread to lymph nodes occurs in Sm1b with vessel invasion, but Kudo[30] found no instance of lymph node involvement in the presence of Sm1a or Sm1b without vessel invasion or intralymphatic tumour.

Radical surgery has been proposed for early colorectal cancer with depression (IIa, IIc and IIa + IIc) and for lesions greater than 10 mm in diameter; the latter are cancers that massively invade the submucosal layer (Sm2 and Sm3). *Table 9* outlines Kudo's advice for the treatment of early colorectal cancer[30]. This can be summarized as standard or advanced polypectomy for all tumours other than those with central depression and raised edges (IIa, IIc and IIa + IIc), which should be treated by radical surgery. However, for all types of early colorectal cancer suspected macroscopically to be associated with massive submucosal invasion, surgery alone is preferred to endoscopic treatment, be this transanal endoscopic microsurgery if the pathological tumour stage is pT_1 or possibly pT_2, or more radical surgery if invasion is beyond this. Indications for radical open surgery after polypectomy include cancer at the margin of the polypectomy[42], lymphatic invasion[16] and inadequate tissue for accurate histological assessment[57].

A recent paper has proposed clinical guidelines for the treatment of early colorectal cancer[10], advising that, if the level of invasion is Sm1, cure can be obtained with local resection or endoscopic polypectomy, regardless of other risk factors. If the level of invasion is Sm2 and the lesion is pedunculated or subpedunculated, endoscopic polypectomy or local resection should be performed initially. Patients with no carcinoma at the margins may be followed without additional surgical treatment, but when the margins are not clear classical bowel resection is advised. If the Sm2 lesion is sessile or the lesion is Sm3, classical resection is necessary, especially if there is lymphovascular invasion or the lesion is located in the rectum. Local excision of rectal lesions by a simple transanal approach or the Yorke–Mason procedure has been complemented by the technique of transanal endoscopic microsurgery. This is suitable for tumours between 6 and 20 cm from the anal verge[57]. For pT_1

Table 9 Treatment advocated by Kudo[30]

Lesion	Treatment
Intramucosal carcinoma	Advanced polypectomy
Minute IIc	Advanced polypectomy
IIb ≥ 5 mm in diameter	Advanced polypectomy*
IIc + IIa and IIa + IIc > 10 mm in diameter	Radical surgery
IIa, Ip, Ips, LST < 3 cm in diameter	Standard or advanced polypectomy

*Rarely has submucosal invasion. LST, laterally spreading tumour; see *Fig. 1* for descriptions of other lesions

lesions excised in this way 5-year survival rates of 47–100 per cent have been reported, with low operative morbidity and mortality rates[58–64]. The 5-year survival rate following local excision is probably better than that with polypectomy for pT_1 tumours (100 *versus* 92 per cent)[65]. Transanal endoscopic microsurgery is associated with a lower recurrence rate than simple transanal excision (4·2–10 *versus* 23 per cent)[58,65–68].

Prognosis

Moreaux and Catala[69] found that the overall 5-year survival rate for patients with colorectal cancer limited to the mucosa or submucosa is 97·6 per cent; the 5-year survival rate with positive lymph nodes associated with an early rectal lesion is 56 per cent and if the lesion is in the colon the rate is 73 per cent. Prognostic indicators are depth of tumour invasion, adverse histopathological type (*Table 6*) and lymph node metastasis. Nodal involvement is associated with a poorer prognosis, with 36 per cent of node-positive patients developing cancer recurrence compared with only 6 per cent of node-negative patients ($P < 0{\cdot}005$). Cumulative survival rate is 73 per cent in node-positive patients, compared with 91 per cent in node-negative patients[11]. Clearly it is vital to identify and to treat adequately patients who have lymph node metastasis.

It would be useful to be able to identify early tumours that are likely to recur, and relevant markers are being sought. Recently *p53* gene nuclear overexpression was shown to be unhelpful as an independent prognostic marker for early colorectal cancer[70]. *MUC* genes, which code for the protein component of epithelial mucins, have been studied and a relationship between *MUC2* and the pathogenesis of certain types of colorectal cancer has been suggested[71]. Several phenotypic patterns have been shown to be more prominent in carcinoma, and others in adenoma. There is an association between peritumoral lymphocytic infiltration and $MUC2^-/MUC1^+$ cancers[72]. Markers may help to determine early cancers at high risk of metastasizing and so aid in planning treatment.

Conclusions

Increasing numbers of early colorectal cancers are being identified by screening and heightened awareness in an ever rising elderly population. This requires a careful consideration of the balance between risk of recurrence and morbidity of treatment. The Japanese have proposed several new classifications which seem at first confusing and which need to be applied and assessed in Western populations, especially the prognostic value of the division of the submucosa into three levels. Simplified versions of such classifications may prove useful in evaluating the results of local excision and provide accurate comparisons between treatment protocols.

Annales de Chirurgie

Digest

Dr Denis Castaing, Editor of *Annales de Chirurgie*, chooses the best from issues six and seven of 1997. A reciprocal digest written by our European Editor, Mr Colin Johnson, is published in the French journal.

Lower limb varicose veins

Good treatment of lower limb varicose veins constitutes a challenge for many surgeons. An important part of number 7 of *Annales de Chirurgie* was dedicated to this old surgical problem.

As reported by Pocard[1] varicose veins of the lower limbs have been described since antiquity in Assyro-Babylonian and Egyptian texts such as the Ebers papyrus, dating from about 1550 BC. Plutarc reported the first varicosectomy which was performed on the Roman general Caïus Marius in 105 BC. The French surgeon of the Middle Ages, Guy de Chauliac, described, in *Chirurgica Magna*, dating from 1350, bandaging for ulcers and cautery or surgical resection for varicose veins. The most remarkable texts were those of Ambroise Paré in the 16th century, using all these techniques for surgical teaching while abandoning many medical treatments based on concepts of disease such as imbalances of 'humours'. The end of the 19th century was the start of a new surgical era with Trendelenburg, Delbert, Mocquot and Mayo, and the development of sclerotherapy, by Pravaz at Wien in 1851.

The second paper by Gillot[2] reported an anatomical study of superficial veins with a calibre of at least 2 mm in 123 limbs (108 normal and 15 with frank varicose disease). The initial network is defined embryologically and subsequent haemodynamic phenomena model the final veins. In particular, the topography of the main perforating veins is relatively fixed. Because of their double antihypertensive valve and aspirating pump function during walking, these vessels drain into saphenous veins. They are beneficial when they return reflux into the deep vessels. Conversely, perforator incompetence contaminates the superficial network as a result of deep reflux. The perforating vessels have a relatively fixed position in relation to the main saphenous collateral veins, their duplicated branches, their communicating veins and the main valves. This results in large junctions typically associating a saphenous valve, one or several collateral veins, one or several communicating veins, and one or several perforating veins. Typical examples are the garter junction for the long saphenous vein and the junction of the tip of the calf for the short saphenous vein. Other haemodynamic levels are situated at various sites, particularly in the leg, reflecting the existence, in some cases, of symmetrical medial and lateral perforating veins. Morphological analysis of 15 limbs with obvious varicose veins of the trunk of the long saphenous vein defined the routes of transmission of reflux to the leg. Finally, the author presents several technical considerations for Doppler operators and surgeons.

The preoperative assessment of varicose veins, which usually requires the use of ultrasonographic methods to specify and localize the various sources of reflux in the saphenous junctions, perforating veins and saphenous branches, was described in the third paper from Baud and Lemasle[3]. Continuous-wave Doppler is the basic technique and duplex scanning provides morphological analysis of the veins and monitors the direction of flow in a precise site. It is particularly useful to study the saphenous junction, perforating veins and deep veins. Colour Doppler imaging offers the advantages of duplex scanning, with visualization of large volumes with blue or red colour-coding according to the direction of flow. All haemodynamic and morphological findings must be reported on a diagram to establish a map of pathological veins.

For a long time, high ligation and stripping of the saphenous trunk was the only technique used to deal with primary varicose veins when surgical treatment was recommended[4]. As duplex ultrasonography has demonstrated that this approach is not effective in many cases, alternative techniques have been proposed and performed. Some of them have not been submitted to randomized and prospective studies. Others, particularly high ligation and stab avulsion of collaterals with preservation of the long saphenous trunk, have been evaluated. The author indicates in which cases high ligation and stripping of the saphenous trunk remains justified and in which situations it is not. All indications must be based on clinical examination and duplex ultrasonography. However, stripping of varicose veins causes pain after operation and sometimes dysaesthesia due to saphenous nerve damage. Ankle wound healing is sometimes painful and often unsightly. Invaginated stripping eliminates some of the drawbacks, but still requires the lower wound and the vein must be left in the case of repeated saphenous rupture. Those two techniques do not allow total saphenous resection in the case of infected ulcers. Constantin *et al.*[5] reported a series of 6157 limbs (3255 patients) operated on by cryosurgery which allows a complete invaginated stripping without an ankle wound. The indication was functional or aesthetic in 5412 cases (88 per cent) and dermitis of hypoderm trophic disorders in 442 cases (7 per cent); 168 limbs (3 per cent) had ulceration and 135 (2 per cent) had superficial venous thrombosis. After operation, one case of sural phlebitis was observed. Fourteen patients had an inguinal wound suppuration. The frequency and intensity of pain and haematomas were decreased. Some 150 of the 168 ulcers were healed after 3 months. The authors concluded that cryosurgery for varicose veins can be used in any circumstances; the lower incision can be avoided thus giving better aesthetic results and cryosurgery has a similar efficacy to the stripping technique.

Ambulatory conservative haemodynamic correction of venous insufficiency is a surgical treatment of superficial venous insufficiency designed to correct the pathological haemodynamic effects of superficial venous insufficiency apparent on standing[6]. This treatment is based on precise preoperative anatomical and haemodynamic mapping performed by duplex ultrasonography, providing preoperative ultrasonographically guided marking. Surgical treatment consists of dividing the hydrostatic pressure column and disconnecting venovenous shunts by ligation–section of the superficial venous network at precise points determined by the preoperative ultrasonographically guided marking. This strategy should achieve a superficial venous circuit draining perfectly into the competent deep venous network. The operation is performed under local anaesthesia as an outpatient procedure and allows immediate resumption of walking, which promotes a good result because of activation of the calf muscle pump. The self-assessment results at 3 years were very good or good in 238 (68 per cent) of 350 in functional terms and 210 (60 per cent) of 350 in aesthetic terms. The authors' conclusions were that this technique is very good provided that reliable preoperative ultrasonographically guided marking and a precise surgical procedure are performed, and that failures are due to poor haemodynamic assessment or inappropriate surgical procedure.

A prospective study of the results of 897 consecutive ambulatory phlebectomies, according to the technique described by Muller in 1966, was reported by Dortu and Constancias-Dortu[7]. Inclusion criteria in this study were based on clinical findings and pulsed Doppler ultrasonography. Patients were reviewed after 1 month and 6 months, then annually. The actuarial rates of good results were 99 per cent at 1 year, 97 per cent at 3 years and 90 per cent at 5 years. In conclusion, the authors recommended that ambulatory phlebectomy has traditional indications (non-saphenous varicose veins, varicose veins of the foot, external pudendal varicose veins) and that ambulatory phlebectomy can also be used as treatment for saphenous varicose veins when the saphenofemoral junction is competent or absent or when the saphenous termination is simple.

Sclerotherapy section consists of a combination of ligations, with section and injection of the proximal and distal segment of the long saphenous vein. This technique is performed under local anaesthesia, 10 cm from the saphenofemoral junction and can be performed as an outpatient procedure. A prospective study of 75 patients (78 limbs operated on, 72 reviewed after 1 year and 65 after 3 years) was reported by Vin *et al.*[8]. Inclusion criteria in this study were incompetent long saphenous vein diameter over 9 mm in older patients whose duplex examination eliminated other leaking points such as anterior or posterior tributaries or the junction, and reflux coming from superficial iliac circumflex veins or from vulvopudendal varicose veins. Sixty-six (92 per cent) of 72 limbs were incompressible without flow or reflux at the saphenofemoral junction level after 1 year and 59 (91 per cent) of 65 limbs after 3 years. Sclerosis with incompressibility without flow or reflux was observed in the lower third of the thigh in 51 (71 per cent) of the 72 limbs after 1 year and in 40 (61 per cent) of the 65 limbs after 3 years, without any clinically detectable underlying varicose recurrence. This technique can be done as an ambulatory procedure and ensures control of saphenofemoral junction reflux. In the majority of reflux cases, the reflux observed in the lower third of the thigh is related to a perforating vein that can feed an underlying varicose network. They were treated by ultrasonographically guided ossifying injection. The authors concluded that the indications for this technique are incompetence of the saphenofemoral junction in older patients with trophic disorders, allowing effective treatment of the source of the reflux with rapid healing of underlying trophic disorders.

Laparoscopic surgery

A series of 98 laparoscopic fundoplications, including seven (7 per cent) for recurrent gastro-oesophageal reflux were reported by Champault *et al.*[9]. Six of these cases occurred within 12 months of surgery. Four were treated successfully by a second laparoscopic procedure. The mean interval between the initial and corrective operation was 10 months. Factors related to failure were technical error, operative inexperience, obesity and the size of the hiatus hernia. Laparoscopic reoperation was relatively straightforward and there were no deaths, but there was an increased risk of pleural effusion. The mean length of hospital stay for reoperations was identical to that of initial operations (4 days). No further recurrences were noted after a mean follow-up of 1 year (range 280–475 days). The authors conclude that early failures following laparoscopic fundoplication can be effectively dealt with by laparoscopic surgery.

A retrospective study was designed by Habib *et al.*[10] to compare the cost of laparoscopic appendicectomy in 114 patients operated on during 1991–1992 and open appendicectomy in 114 patients operated on during 1989–1990. Patients were matched for sex, American Society of Anesthesiologists (ASA) score and age into two homogeneous series. Costs of accommodation, operation and time off work were calculated by the observed costs method to assess daily cost of the inpatient unit, hourly cost of the operating room–recovery ward and the patient's consumption. A mean specific cost was added in the case of laparoscopic appendicectomy. A significant difference was observed in operating time (mean(s.d.) 43(18) min for laparoscopic appendicectomy *versus* 64(28) min for open appendicectomy; $P<0{\cdot}01$), postoperative stay (5·4(4·5) *versus* 4·3(2·2) days; $P<0{\cdot}02$), and time off work (31(10) *versus* 22(7) days; $P<0{\cdot}01$). The mean(s.d.) total cost of the treatment was 26 712(8829) French francs for laparoscopic appendicectomy and 23 040(6365) French francs for open appendicectomy ($P<0{\cdot}01$). The higher cost of the operation in the case of laparoscopic appendicectomy was not compensated by the reduction in accommodation costs. A clinical benefit in terms of reduction of pain and local complications has been reported in the literature. The cost of hospitalization is higher with laparoscopic appendicectomy, but the cost of the time off work is decreased. The conclusion was that laparoscopic appendicectomy provides clinical benefit in all patients and an economic benefit in patients with a professional activity.

From December 1989 to May 1995, a prospective study of laparoscopic cholecystectomy was carried out by Colonval *et al.*[11] to assess the reliability and safety of this method in cases of acute cholecystitis. During this period, 1453 patients underwent laparoscopic cholecystectomy. Acute cholecystitis was diagnosed in 280 patients, based on clinical history and macroscopic lesions. Only 221 patients (15 per cent) were included in the study after positive histology was obtained (86 men; 135 women). The mean age was 62 (range 20–90) years. Sixty-two patients (28 per cent) were classified as ASA III and IV. The mean interval between the first symptoms and operation was 10 (range 1–53) days. The mean operating time was 130 (range 45–420) min. Conversion to an open procedure was necessary in 22 patients (10 per cent). The operative mortality rate was 1 per cent (two patients classified ASA grade IV) and the overall morbidity rate was 13 per cent. A bile duct injury occurred in one patient. The authors conclude that laparoscopic cholecystectomy for acute cholecystitis is a safe procedure, when performed by operators experienced in laparoscopic surgery.

Laparotomy has no benefit in 5–39 per cent of patients suffering from penetrating abdominal trauma[12]. In a prospective study to determine the value of laparoscopy in the management of such patients, 13 patients (11 men; mean age 32 years) underwent laparoscopy for abdominal knife wounds. Two patients had a non-penetrating abdominal wound (one with a pneumothorax and one with a parietal haematoma). Eleven patients had a peritoneal penetrating wound and only four of them had lesions that required surgical treatment (two intestinal wounds, one gastric wound and one coeliac artery disruption). No treatment was required in three patients (one wound of the intestinal serosa and two superficial hepatic wounds). In the remaining six patients no visceral wound was found. There was no death or morbidity. No lesions were missed at laparoscopy and laparoscopy avoided unnecessary laparotomy in nine of 13 patients. The authors suggest that laparoscopy is a reliable method for the management of patients with abdominal wounds, allowing a very sensitive and specific diagnosis of penetration and visceral injuries. In some cases, it allows laparoscopic treatment of the visceral injury.

Background Biliary obstruction in the rabbit causes increased release of atrial natriuretic peptide (ANP). Circulating bile, raised biliary pressure or absence of bile in the duodenum may be implicated in this hepatocardiac syndrome.

Methods An experimental model was developed to elucidate the mechanism linking obstructive jaundice and increased plasma ANP. Hepatic and renal function, biliary tree pressure and ANP plasma concentrations were investigated in conscious rabbits 4 and 24 h after common bile duct ligation, biliovenous shunting or external drainage via a biliary fistula.

Results Bilirubin concentration increased after bile duct ligation and creation of a biliovenous shunt. Plasma creatinine increased abruptly in rabbits with a biliovenous shunt. At 4 h, the ANP increase in animals with a biliovenous shunt was ninefold that observed after bile duct obstruction while no change was noted after external biliary diversion (mean 350 *versus* 45 *versus* 9 fmol/l; $P < 0{\cdot}01$). Relief of biliary tree obstruction was associated with a return of ANP levels towards basal normal values.

Conclusion Raised plasma ANP in obstructive jaundice is not the result of an increased biliary pressure *per se* or absence of bile in the proximal duodenum but of the passage of bile components to the circulation.

Extracellular volume depletion may be an important factor influencing renal function in obstructive jaundice[1,2]. In conscious rabbits with bile duct ligation, volume depletion has been observed to be associated with profound hypodipsia, hypophagia and inappropriate diuresis[3,4]. These derangements of water and sodium metabolism are associated with high plasma concentrations of renin, aldosterone, vasopressin and atrial natriuretic peptide (ANP)[4]. The latter is the result of increased release of this peptide from the heart[4]. Furthermore, increased atrial staining for ANP and increased atrial content of this peptide hormone were noted in jaundiced rabbits when compared with sham-operated controls[5]. While increases in plasma renin and aldosterone are a logical endocrine response to a reduced extracellular water compartment, high plasma concentrations of ANP seem to be a primary non-compensatory abnormal response of atrial cardiocytes to biliary obstruction[4,5].

The mechanism of ANP release in obstructive jaundice is not known. Increased biliary pressure, circulating bilirubin or absence of bile in the duodenum can theoretically all be involved. In the present study, a new experimental model is reported which permits further elucidation of the mechanism of ANP release.

Materials and methods

Animal model

Twenty-two male New Zealand rabbits with weights ranging between 2650 and 3900 (mean 3200) g were kept in individual cages and given free access to water and chow (Panlab, Barcelona, Spain). After 1 week of adaptation they were submitted to a surgical procedure under general anaesthesia induced with subcutaneous Ketolar 100 mg/kg (Parke Davis, Madrid, Spain), Thalamonal 0·5 mg/kg (Syntex Latino, Barcelona, Spain) and atropine 0·5 mg. Catheters were inserted into both jugular veins (*Fig. 1*); the right was used for blood sampling and the left for drainage of bile from the gallbladder (biliovenous shunt). Both jugular catheters were tunnelled to the occipital region where they were secured to the skin with 000 silk sutures. The common bile duct was ligated with 0000 silk close to the duodenum through an upper midline incision. Catheters were placed in the gallbladder and within the duodenal lumen (*Fig. 1*), and then exteriorized and connected to a three-way stopcock. An additional line was eventually connected to catheter B to create a biliovenous shunt. Bile flow was directed through the three-way stopcock either to the duodenum or to catheter D. By occluding catheter C, complete biliary obstruction was produced and by leaving it open complete external biliary diversion was obtained. The laparotomy wound was closed with 000 silk sutures. Cloxacillin 250 mg was administered intravenously at the beginning and end of the operation. After operation the animals were equipped with a jacket (Alice King Chatam, Los Angeles, California, USA) to prevent damage to the catheters.

Experimental protocol

On the fourth day after operation, animals were lightly sedated with diazepam 5 mg/kg and Thalamonal 0·5 mg/kg and randomized into three groups: bile duct obstruction (group CBDL, $n = 8$); biliovenous shunt (group BVS, $n = 8$) and biliary diversion via a external biliary fistula (group BF, $n = 6$). At 0, 5, 10, 15, 20 and 30 min, and 1, 2, 4 and 24 h after biliary obstruction, biliovenous shunting or biliary diversion, biliary pressure was recorded through the left jugular catheter. Blood samples were obtained to determine osmolality and levels of urea, creatinine, sodium, potassium, total bilirubin and alkaline phosphatase (Technicon Instruments, Tarrytown, New York,

Paper accepted 22 September 1997

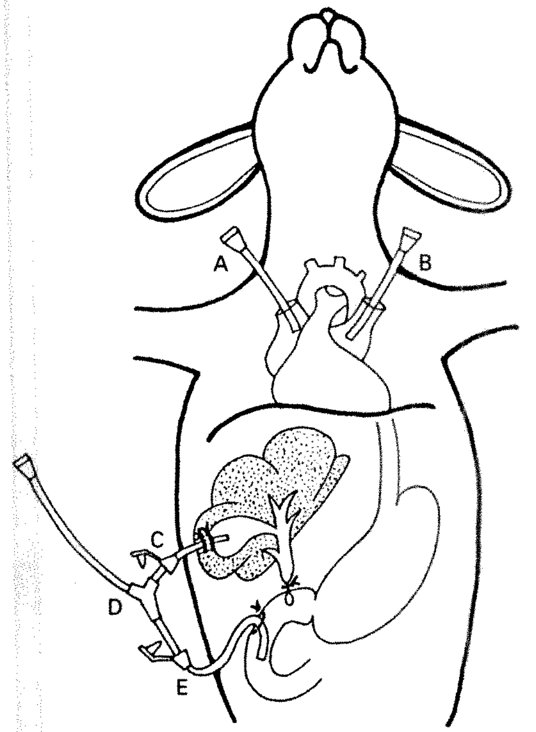

Fig. 1 Physiological preparation for creating complete biliary obstruction, a biliovenous shunt or a biliary fistula. A, right jugular catheter; B, left jugular catheter; C, gallbladder catheter; D, central venous pressure catheter to record biliary pressure; E, duodenal catheter

USA) at time 0, and after 1, 2, 4 and 24 h. ANP was also determined in these blood samples by radioimmunoassay as described previously[3]. A volume of saline similar to that of each blood sample was infused through the catheter to avoid extracellular volume depletion. Also, the bile lost in group BF was replaced with an equal volume of intravenous saline. In group CBDL, the duodenal catheter obstruction was released at the end of the 24-h study period to restore bile flow from the gallbladder to the duodenum. Biliary pressure was recorded again and blood samples were taken at 48 and 72 h for biochemical analysis and ANP measurements. All the animals were killed humanely at the end of the study and a post-mortem examination was carried out to check the patency of the catheters, the absence of mechanical complications and the presence of cholestasis.

Statistical analysis

Results are expressed as mean(s.d.). Intergroup analysis at 4 and at 24 h after biliary tract manipulation was carried out using the factorial analysis of variance test and Snedecor's F-value; and the two-tailed Student's *t* test for paired and unpaired data as required. Data processing was done with a Macintosh II computer (Apple, Cupertino, California, USA) and the Statview II statistical package (Abacus Concepts, Berkeley, California, USA). Statistical significance was set at $P < 0\cdot05$.

Results

Basal metabolic variables (serum electrolytes, renal and liver function tests and ANP levels) were similar in all three experimental groups at the beginning of the study, 4 days after surgical preparation.

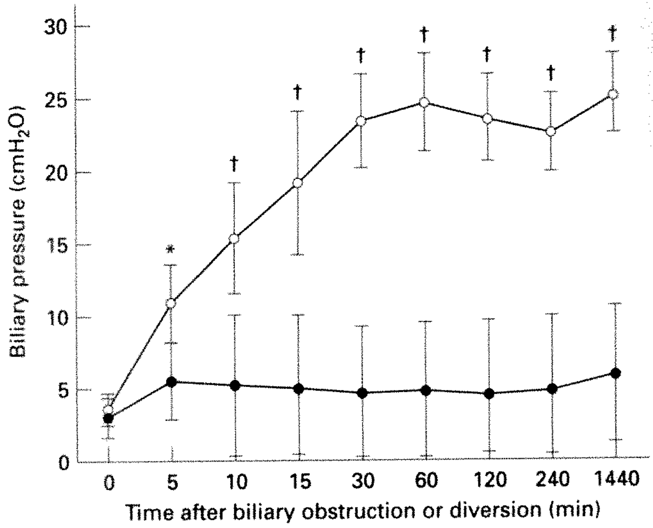

Fig. 2 Mean(s.d.) biliary pressure at time 0 (baseline value) and after common bile duct obstruction (○) and biliovenous bypass (●). $^*P < 0\cdot05$, $^\dagger P < 0\cdot001$ *versus* BVS group (Student's *t* test)

Biliary pressure

After obstruction of the duodenal catheter, the pressure within the biliary tree increased rapidly to attain its maximum value at 1 h (*Fig. 2*). After releasing the obstruction, the pressure returned to its normal baseline value: 4·4(1·3) cmH$_2$O at 48 h and 3·8(1·3) cmH$_2$O at 72 h. In group BVS, biliary pressure did not change and remained around baseline value throughout the study.

Obstructive jaundice

In group CBDL there were significant increases in bilirubin and alkaline phosphatase levels at 4 and 24 h (*Tables 1* and *2*) which returned to normal after restoration of bile flow. In group BVS bilirubin values were significantly higher than those observed in group CBDL but the alkaline phosphatase level remained normal.

Renal function

In groups CBDL and BF there were no significant changes in urea concentration and in plasma electrolytes at 4 or 24 h. Urea and creatinine plasma concentrations increased significantly in group BVS, attaining values characteristic of acute renal failure at 24 h.

Atrial natriuretic peptide

After duodenal catheter obstruction in group CBDL, the ANP plasma concentration increased steadily reaching a threefold increase over basal values from 2 to 24 h (*Fig. 3*). After bile flow was re-established, ANP plasma concentrations tended to return to normal, and at 24 and 72 h they were no different from basal values: 19·8(14·4) and 17·7(17·9) fmol/l respectively. In group BVS, ANP concentration showed a ninefold rise 4 h after biliary venous diversion and remained increased throughout the 24-h study period. In group BF, ANP concentration was unchanged.

Discussion

The pathogenesis of renal dysfunction associated with obstructive jaundice and acute cholangitis is becoming progressively clarified. Extracellular volume depletion has been reported both in animals and in humans with biliary obstruction[1,2]. In rabbits, plasma volume is reduced by 15 per cent 12 days after common bile duct ligation[1] and this is associated with water and sodium retention[6]. Thus, a reduced extracellular water compartment, with marginal hypovolaemia, appears to be a significant factor predisposing to renal failure, particularly when associated with perioperative haemorrhage, hypotension[7], and administration of diuretics[8] or nephrotoxic drugs[9]. The need for appropriate preoperative hydration of patients undergoing surgery for biliary obstruction has been underlined by Parks *et al.*[10]. These authors compared hydration alone with hydration and dopamine and found no differences in the incidence of postoperative renal dysfunction after these treatments.

In animal models, water and sodium depletion are linked to hypodipsia, hypophagia and inappropriate diuresis and natriuresis[3,11]. Fractional excretion of sodium is increased 4 h after bile duct ligation[12]. The ANP plasma concentration has been found to be raised in rabbits with obstructive jaundice[3–5] and therefore this peptide could be implicated in the loss of the thirst mechanism and sodium appetite, and in the inappropriate natriuresis observed in these animals[3,4]. The rise in ANP plasma concentration has been confirmed in the present study. Furthermore, this increase was found to be reversible, depending on the relief of biliary obstruction. In contrast with these findings, ANP release has not been found to be raised in rats after 2–5 weeks of biliary obstruction[13] (and unpublished results from Vakil *et al.*). In one study, however, ANP messenger RNA was increased in the atria of bile duct ligated rats as well as glomerular ANP receptor density[13]. In the dog, ANP increase has only been detected after 5–6 weeks of jaundice[14]. It has to be taken into account, however, that rats and dogs develop cirrhosis and ascites following bile duct obstruction ('wet models'), while the rabbit and the baboon show a cholestatic syndrome more akin to the human condition ('dry models'). Another factor that could explain differences in ANP plasma concentrations is timing between biliary obstruction and blood sampling. In these studies, ANP was not determined in the early phases of obstructive jaundice.

The cause of raised plasma concentrations of ANP in obstructive jaundice is not known. The level of this hormone has been found to be increased in diseases associated with extracellular volume expansion and atrial distension[15]. Thus, in obstructive jaundice increased ANP concentration appears to be a paradoxical phenomenon since this disease is characterized by hypovolaemia rather than hypervolaemia; therefore, other mechanisms for ANP release should be operative. Increased pressure within the biliary tract and/or the direct action of some bile component on the right atrium were thought to be the two mechanisms possibly linking biliary obstruction to ANP release. Also, recent reports suggest that ANP may be a regulatory gastrointestinal peptide since it has been identified in the upper gastrointestinal tract[16]. According to the results of the present study, however, neither increased biliary pressure *per se* nor the absence of bile salts in the duodenum can be incriminated as a cause of increased plasma ANP concentration. Thus, it appears that the presence of bile components in the blood is essential to the ANP response.

Topuzlu and Stahl[17] found an increased diuresis and natriuresis after direct intravenous infusion of bile. A similar renal response was found by Levy and Finestone in dogs during 4 h of common bile duct obstruction[12]. These authors were able to reproduce the natriuretic response to biliary obstruction in healthy dogs by cross-circulation and postulated the existence of a humoral mechanism. The current study shows that the presence of bile products in the circulation is a very powerful stimulant of ANP release. This peptide could well be the humoral factor postulated by these other investigators.

At present the mechanism whereby bile components release ANP from the heart can only be speculated upon. The presence of bile products in the blood may diminish cardiac contractility and may result in increased ANP synthesis through stretching of the atria. ANP plasma concentrations appear to accurately reflect left ventricular function and seem to be very sensitive to even minimal asymptomatic myocardial dysfunction[18]. In dogs with a choledochocaval shunt, the Haifa group has shown a reduction of the left ventricle contractility[19], although they were unable to detect ultrastructural myocardial damage in this model or in dogs with bile duct ligation[20]. More recently, Jacob *et al.*[21] have reported a decreased myocardial contractility in rats 3 days after common bile duct ligation, independent of changes in the number or responsiveness of beta adrenergic receptors. Direct biliovenous reflux, however, appears to magnify the adverse consequences of biliary obstruction. Reflux results in much higher plasma bilirubin and ANP levels and leads to acute renal failure either through a direct toxic effect of bile components on the renal parenchyma and/or through arteriolar vasoconstriction mediated by prostaglandins[22]. Thus, although bile passes to the venous circulation during biliary obstruction, the liver parenchyma probably acts as a filter by either reducing the hepatic synthesis of biliary products or clearing them before they enter the venous circulation.

In summary, this study shows that ANP is released by the presence of bile components in the plasma and that neither raised biliary tree pressure nor absence of bile salts in the proximal gut can be incriminated as the cause of increased ANP concentration. Decreased myocardial contractility and auricular stretching may be the factors linking circulating bile and increased heart endocrine activity.

Total vascular exclusion of the liver for the resection of lesions in contact with the vena cava or the hepatic veins

T. BERNEY, G. MENTHA and Ph. MOREL

Clinic of Digestive Surgery, Geneva University Hospital, 24 rue Micheli-du-Crest, 1211 Geneva 14, Switzerland
Correspondence to: Dr T. Berney

Background This study reviews experience with total vascular exclusion of the liver (TVE), for the resection of tumours in contact with the hepatic veins or the vena cava.

Methods A retrospective study was carried out of 366 hepatic resections performed over 13 years. Forty-one patients (11 per cent) were operated under TVE.

Results Twenty-four patients were operated for malignancy and 17 for benign disease. Major hepatectomy was performed in 26 patients and minor hepatectomy in 15. The technique allowed vascular repair in eight patients. Median intraoperative blood transfusion was 2 (range 0–26) units; 14 patients required none. Median duration of TVE was 29 (range 5–58) min. No deaths occurred. Significant complications occurred in ten patients. Morbidity was related to the malignant nature of the lesion, duration of surgery and volume of blood transfusion, but not to duration of TVE.

Conclusion TVE facilitates resection of critically located hepatic lesions with safety and minimal blood loss. Within the limits of 1 h, prolonged TVE does not increase morbidity.

The limits of hepatic surgery have been extended recently thanks to advances in anaesthesiological management, improved surgical techniques and technologies, and better understanding of the functional anatomy of the liver[1–3]. It has long been recognized that intraoperative bleeding was of foremost importance in the development of perioperative morbidity and death[4–8]. Several methods intended to limit bleeding have been developed with the first description of portal triad clamping by Pringle in 1908[9], which led to the development of total vascular exclusion of the liver (TVE) by Heaney *et al.* in 1966[10]. Since then, Huguet and colleagues[11–13] have better characterized and widely advocated the use of TVE, showing good tolerance of the liver to haemodynamic changes and warm ischaemia. TVE provides control of the hepatocaval connection, and thus allows resection of tumours adjacent to the vena cava and the hepatic veins with limited risk of massive haemorrhage or air embolism, which are the two major hazards in this type of surgery.

Whereas TVE is performed almost routinely in most institutions where it is used[14,15], the present authors use it exclusively for resection of lesions situated in contact with the hepatocaval connection. As few series of hepatectomies under TVE for this type of tumour are available, experience with TVE has been reviewed, with special regard to death and morbidity and their relation to blood loss and duration of liver ischaemia.

Patients and methods

Patients

From February 1984 to February 1997 (13 years), 366 patients underwent liver resection in this institution. For all patients, resectability was assessed by computed tomography, selective coeliomesenteric angiography with late-phase portography and, for some of the more recent cases, magnetic resonance imaging. Fifty-seven patients with lesions situated in close contact with the hepatic veins or the inferior vena cava were considered for resection under TVE. For 14 of these patients, a complete dissection to prepare for TVE was done but TVE was not performed, because it appeared in the process of surgery that safe hepatectomy could be achieved without recourse to it. Occlusion of the vena cava was not performed in two patients, and surgery with additional aortic clamping was necessary in one patient, because of poor haemodynamic tolerance. Thus 41 patients underwent hepatectomy under TVE during this period. Median patient age was 49 (range 20–73) years. There were 22 women and 19 men. Indications for liver resection are shown in *Table 1*. Three patients had evidence of liver cirrhosis, and the other 38 had a non-cirrhotic liver parenchyma. American Society of Anesthesiology (ASA) grade was I or II in all patients but five who were graded ASA III, and one ASA IV.

Relationship of tumours with the hepatocaval confluence

Only patients with lesions in close contact with either element of the hepatocaval confluence were considered for TVE. The tumours involved the vena cava on 21 occasions, the middle hepatic vein 24 times, the right hepatic vein 16 times and the left hepatic vein 11 times. More than one vein was involved in the

majority of patients. Notably, in three patients the tumour was set anteriorly against the vena cava and in close contact with all three elements of the venous hepatic pedicle. In addition, TVE allowed repair of tears on a hepatic vein in seven patients, and reconstruction of a narrowed, single remaining left hepatic vein in one case.

Operative technique

The surgical technique was that described by Huguet *et al.*[13]. In general a bilateral subcostal incision was used (34 patients) completed in one case with a right thoracotomy. Occasionally, mostly in early cases, a vertical midline incision was performed (seven patients), completed in six patients with a right thoracic extension and in one with a transverse incision. From 1988, intraoperative ultrasonography was performed routinely to determine the exact vascular relationships of the tumour to be removed. All the hepatic ligaments were divided to allow complete mobilization of the liver and exposure of the whole retrohepatic vena cava. TVE was prepared by carefully dissecting the suprahepatic and infrahepatic vena cava, and right adrenal veins and accessory hepatic veins were ligated if necessary to allow complete venous control during clamping. Unless an atypical resection was planned, control of the hilar structures was first performed, with ligation of the portal and arterial elements, after trial clamping to assess discoloration of the parenchyma to be removed. In the interests of safety, biliary tract elements were usually ligated during parenchymal transection. Clamps were always applied in the same sequence: infrahepatic vena cava, portal triad and suprahepatic vena cava. If a left hepatic artery was present, it was controlled by a fourth clamp in order to completely interrupt arterial blood flow to the liver. A trial clamping of 2–5 min was then done, to ascertain haemodynamic tolerance. Clamps were released for a few minutes before proceeding with liver transection, which was done by carefully crushing the liver parenchyma with a Kelly forceps ('kellyclasie'), with ligation of vascular structures greater than 2 mm in diameter and electrocoagulation of the smaller ones. When a long-lasting resection was planned, the first stages of the dissection were performed without vascular exclusion or with single portal triad clamping, in periods no longer than 12 min, with 5–10-min intervals, until TVE was necessary because of the vicinity of the hepatic veins or the vena cava. After completing the resection, the clamps were removed in the reverse order of their application. Haemostasis of the raw surface of the liver was assured by argon beam coagulation and completed by application of a biological fibrin glue (Tisseel/Tissucol, Immuno AG, Vienna, Austria) and sealing with haemostatic material (Tabotamp, Johnson and Johnson, Skipton, UK) and a patch of omentum if available. Closed drainage was established only when a biliary leak could not be ruled out absolutely.

Couinaud's description of the functional anatomy of the liver was used for designation of the segments and definition of hepatectomies[1,16].

Data collection and analysis

All medical records of patients considered for TVE were reviewed retrospectively and demographic, laboratory, intraoperative, histopathological and clinical data were collected.

Significant morbidity was defined as complications of grade II or more according to Clavien *et al.*[17]. Briefly, this applies to patients with life-threatening complications that required surgical or drainage procedures, that caused residual disability or that prolonged hospitalization over twice the median postoperative hospital stay. Perioperative death was defined as that occurring during the hospital stay or up to 30 days after operation if the patient was discharged earlier.

Several variables were compared for their roles in morbidity, intensive care unit stay and postoperative hospital stay. Mann–Whitney *U* test was used for comparison of continuous variables, and χ^2 with Yates' correction or Fisher's exact test for discrete variables when applicable. Correlation was assessed by linear regression and Pearson's coefficient was calculated. $P<0{\cdot}05$ was considered significant.

Results

Types of resection for the 41 patients are shown in *Table 2*. Resections were called major if three segments or more were removed according to Couinaud's classification[16]. Median operating time was 6 h (range 2 h 20 min to 12 h) and median duration of TVE was 29 (range 5–58) min). Intermittent single portal triad clamping was used in the course of resection for 13 patients before undertaking TVE. One or two periods of clamping of 8–15 min were carried out in these patients. Median intraoperative blood transfusion was 2 (range 0–26) units of packed red blood cells, and 14 patients required none.

There was no intraoperative or postoperative death. Twenty-one significant complications occurred in ten patients and are listed in *Table 3*. One patient developed transient severe postoperative liver failure with encephalopathy. Transient moderate hepatocellular failure (prothrombin time less than 50 per cent) without clinical symptoms was observed in 11 additional patients. Renal failure (creatinine level above 125 μmol/l) was observed in one patient with pre-existing moderate chronic renal failure, but the patient's blood creatinine level remained stable. These patients spent a median of 2 (range 0–7) days in the intensive care unit, and were discharged from hospital after a median postoperative stay of 13 (range 7–65) days.

Several risk factors were studied for occurrence of postoperative complications and results of the analysis are shown in *Table 4*. The only significant differences between patients with or without complications were in the malignant nature of the lesion, duration of surgery and volume of blood transfusion. Duration of surgery and amount of blood transfused were not independent variables as they were correlated ($r=0{\cdot}43$, $P<0{\cdot}005$).

Table 2 Type of liver resection performed under total vascular exclusion

Operation	No. of patients
Major resection	
Extended right hepatectomy*	6
Right hepatectomy*	8
Extended left hepatectomy*	4
Left hepatectomy*	8
Total	26
Minor resection	
Left lobectomy*	1
Bisegmentectomy III–IV	1
Bisegmentectomy IV–VIII	1
Segmentectomy VII	1
Segmentectomy IV	1
Tumorectomy	10
Total	15

*In the American literature[16,18], extended right hepatectomy corresponds to right trisegmentectomy (segments IV–VIII with or without segment I), right hepatectomy to right lobectomy (segments V–VIII), extended left hepatectomy to left trisegmentectomy (segments I–IV, with or without segments V, VIII), left hepatectomy to left lobectomy (segments II–IV), and left lobectomy to left lateral segmentectomy (segments II and III)

Table 3 Significant complications in ten patients operated under total vascular exclusion of the liver

Complication	No. of patients
Abdominal	
Biliary leak	3
Ascites	2
Hepatic necrosis*	1
Acute pancreatitis	1

Several patients had more than one complication. *This patient developed necrosis of segment II after a right trisegmentectomy for hepatocellular carcinoma

Table 4 Risk factors for the development of complications in patients operated under total vascular exclusion of the liver

Risk factor	Patients with complications ($n = 10$)	Patients without complications ($n = 31$)	P
Mean age (years)	51	48	n.s.‡
Sex ratio (M:F)	4:6	15:16	n.s.§
Mean ASA grade	2·0	1·7	n.s.‡
Cirrhosis	1	2	n.s.§
Malignancy	9	15	< 0·05§
Major resection*	7	19	n.s.§
Mean transfusion requirement (units)†	5·2	3·5	< 0·05‡
Mean duration of vascular exclusion (min)	29	32	n.s.‡
Mean duration of operation (h)	8·2	5·4	< 0·01‡

*Three or more segments of Couinaud removed; †units of packed red blood cells transfused at operation. ASA, American Society of Anesthesiologists; n.s., not significant. ‡Mann–Whitney U test; §χ^2 or Fisher's exact test

Duration of vascular exclusion was not found to be a risk factor for complications, nor did it correlate with either intensive care unit stay ($r = 0·1$, $P > 0·5$) or postoperative hospital stay ($r = 0·06$, $P > 0·5$).

Discussion

Advances in the techniques of vascular exclusion of the liver have dramatically improved achievements in the performance of surgery for tumours of the hepatocaval connection. Since clamping of the portal triad alone[9] did not prevent hepatic venous bleeding or air embolism, new ways of vascular exclusion had to be devised. The first techniques described involved cross-clamping of the aorta[10] because of concerns about haemodynamic tolerance, or hypothermic perfusion of the liver[19] because of concerns about tolerance to warm ischaemia. Since then, Huguet and colleagues[20,21] have shown that aortic clamping is seldom necessary, as patients generally adapt well and quickly to the haemodynamic changes observed, and that the hepatocytes can tolerate periods of normothermic ischaemia in excess of 1 h[22]. A modern technique, which is used in this institution, has emerged from this pioneering work and allows resection of lesions in close contact with the vena cava and the hepatic veins with a very limited risk of air embolism or massive haemorrhage. These hazards would have made impossible the safe resection of most of the tumours reported here, if TVE had not been available. In many instances, achievement of a bloodless operative field has allowed close dissection or repair of the hepatic veins or the vena cava and has limited the blood transfusion required in these patients. That 14 of 41 patients in this series did not require blood transfusion is noteworthy, especially for critically located tumours. In addition, a bloodless operative field allows easy and precise dissection and reduces the duration of surgery, which is illustrated by the fact that volume of transfusion and duration of operation are interdependent risk factors. A flawless technique is mandatory if one is to achieve total venous control. This requires adequate positioning of the caval clamps to exclude all venous collaterals, and might involve ligation of adrenal, phrenic, lumbar and accessory hepatic veins. Recognition and clamping of a possible left hepatic artery should not be neglected either[13].

Haemodynamic tolerance to TVE was excellent in most patients. Transient and moderate decreases in systemic blood pressure were observed. A slight vascular overload is essential and was always obtained before vascular occlusion to secure good haemodynamic tolerance, as it has been shown that clamping of the vena cava induces a 50 per cent decrease in cardiac index[20,21]. Venous occlusion was abandoned in only two patients because of persisting severe hypotension. Bad haemodynamic tolerance can indicate the need for associated aortic clamping, a technique used routinely in other institutions[15]. However, reported complications of spinal cord ischaemia, renal failure or aortic injury[23] make routine aortic clamping inappropriate in view of the excellent haemodynamic tolerance generally obtained without aortic occlusion.

The concept of poor tolerance of the liver to warm ischaemia has been challenged recently and it has been shown that hepatic vascular exclusion can be performed safely for up to 1 h. Duration of ischaemia up to 2 h without major detrimental effects other than transient hepatic failure has even been reported[14,22,24]. This series, in which nine patients had vascular exclusion exceeding 45 min, confirms this good tolerance, and shows that, within the limit of 60 min, there is no correlation between duration of ischaemia and morbidity. It appears that risks related to haemorrhage are of a greater concern than those related to the length of ischaemia. Thus, for critically situated and not easily resectable lesions, it is safer to continue vascular exclusion, within a 1-h limit, until complete resection is achieved, rather than take the chance of significant bleeding for the sake of a shorter period of ischaemia. Furthermore, it is possible to reduce the duration of continuous warm ischaemia, by initiating parenchymal transection without vascular exclusion or with intermittent portal triad clamping until the hepatocaval intersection is reached as used in 13 patients in this series. Intermittent portal triad clamping can be done, if needed, intermittently in successive periods of up to

20 min for more than 2 h[25]. Finally, whenever TVE is planned after analysis of radiological images, preparatory dissection of the vena cava is done, but TVE is actually carried out only if intraoperative conditions require it.

Resection of a cirrhotic liver is limited in terms of extent of resection and duration of vascular exclusion. Cirrhosis precludes major hepatectomy and prolonged vascular exclusion because of the high risk of fatal hepatocellular failure[26-28]. Therefore, whenever a major hepatectomy is planned in patients under suspicion of abnormal liver parenchyma (i.e. patients with B virus or C virus chronic hepatitis, or after chemotherapy or radiotherapy), a biopsy of the planned remnant parenchyma is done, and if cirrhotic the surgical strategy is adjusted. However, a recent paper reported no deaths in a series of selected patients with cirrhosis undergoing liver surgery under TVE[28].

The mortality rate of zero in this series confirms the safety of the technique and compares favourably with other studies[15,18,22,23,28,29]. On the other hand, a morbidity rate of 24 per cent (ten of 41 patients) cannot be dismissed as trivial, but it is none the less acceptable in view of the difficult resections involved here, as confirmed by the duration of these operations. A recent prospective randomized trial comparing intermittent clamping of the portal triad and TVE has demonstrated the lower morbidity of the former technique[30]. However, TVE in this series has been found to be safe, with no deaths, acceptable morbidity, and a remarkable limitation of blood loss and transfusion requirements.

---

Background Systemic antibiotics are administered frequently after hepatectomy to prevent infective complications, but their effectiveness is uncertain.

Methods A total of 127 patients with liver tumours were prospectively randomized into two groups after hepatectomy: in group 1 (62 patients) no antibiotics were given until the appearance of infective complications; in group 2 (65 patients) intravenous cephazolin 1 g every 6 h and gentamicin 80 mg every 8 h were given for 7 days. On the day before surgery all patients received bowel preparation by clear liquid diet and oral antibiotics (neomycin 1 g and erythromycin 1 g, given together in three doses).

Results The infective complication rate was 23 per cent in both groups ($P = 0{\cdot}95$). The hospital costs were higher in group 2 ($P < 0{\cdot}001$). Of the group 1 patients, 51 (82 per cent) did not require antibiotic treatment. No patient in either group died after hepatectomy.

Conclusion Postoperative systemic antibiotics cannot prevent infective complications, and their routine use after hepatectomy is unnecessary and costly. The use of antibiotics should be delayed until infective complications and persistent septic symptoms occur.

In spite of low postoperative mortality, the morbidity rate of liver resection is between 20 and 50 per cent[1-7]. Among the complications, infection is common and potentially fatal[3-7].

Antibiotic prophylaxis has been reported as unnecessary following clean surgery unless a prosthesis is used or the patient is immunocompromised[8,9]. Although liver resection is not a heavily contaminated procedure[8], it usually requires a long operating time and results in significant blood loss[1-7,10]. Many catheters are inserted for perioperative haemodynamic and urinary output monitoring, and these catheters may be the source and site of infection[8].

After liver resection, large dead spaces and areas of devitalized tissue on the cut surface are present[5,6]. If contaminated with bile or bacteria, intra-abdominal infection readily occurs[5-7]. Moreover, liver resection may reduce the functional capacity of the reticuloendothelial system[5,7] and cause translocation of intestinal bacteria to the systemic circulation[11]. Thus, the posthepatectomy infection rate may be high, and postoperative systemic antibiotics are administered routinely in most centres[1,3-7]. However, the efficacy of this strategy remains uncertain[7] in the absence of controlled data. This paper reports a randomized clinical trial of systemic antibiotics after liver resection to determine its value.

Patients and methods

Between October 1994 and September 1996, 127 consecutive patients who underwent elective liver resection for hepatic lesions were enrolled in the study. Patients who required hepatectomy for emergency conditions (such as liver trauma or ruptured liver tumour), who had associated septic circumstances (such as hepatolithiasis or hilar cholangiocarcinoma[7,12,13]) or synchronous metastatic gastrointestinal cancers[14] were excluded. Informed consent was obtained from each patient before surgery.

Preoperative assessments included liver function testing, indocyanine green (ICG) clearance testing and imaging studies (including abdominal ultrasonography, computed tomography (CT) and angiography)[15]. Child's grading for liver cirrhosis[16] was applied to each patient. On the day before surgery all patients received a clear liquid diet and oral antibiotics (neomycin 1 g and erythromycin 1 g, given together at 13.00 hours, 14.00 hours and 22.00 hours) for bowel preparation as suggested by Condon and Wittmann[9].

Couinaud's definition of liver segmentation[17] was used for reporting the tumour location and the extent of hepatectomy. The amount of liver resection was determined by the preoperative liver function and ICG clearance testing[1,2,15].

All operations were performed under general anaesthesia with endotracheal intubation, and central venous, arterial and urethral catheters were inserted. Cholecystectomy was performed routinely before hepatectomy. Liver parenchymal dissection was carried out by the Kelly fracture method, usually under intermittent occlusion of hepatic inflow blood[1,2,15]. After removal of all lesions, the cut surface of the liver was packed with Surgicel (oxidized cellulose; Johnson and Johnson Medical, Arlington, Texas, USA) and surrounded with closed suction drains[5]. The drains were retained until the drainage fluid appeared serous and the amount was less than 50 ml per day.

Immediately after operation, all patients were randomized into two groups without regard to patient background or operative procedure. Group 1 comprised 62 patients to whom no antibiotics were given after the operation. Group 2 consisted of 65 patients who received intravenous cephazolin 1 g every 6 h and gentamicin 80 mg every 8 h for 7 days beginning immediately after operation. These antibiotics were chosen because of possible contamination with bile during hepatectomy[3,5-7], as well as their high biliary secretion[18] and high efficacy in biliary surgery[19].

As with previous reports[3-9,18,20-22], infective complications were defined as positive culture of pathogenic micro-organisms from infective sites, such as wound, tip of central venous catheter,

Paper accepted 3 July 1997

urinary or respiratory tract, and abdominal cavity. Sensitivities to various antimicrobial agents were determined when bacteria were cultured.

If postoperative septic symptoms (fever, chills, undue wound pain or leukocytosis) occurred, the potential infective sites were examined, and management of infective complications was instituted immediately after diagnosis. Management and treatment involved opening the infected wound, removing the infected catheter or draining the intra-abdominal abscess. Cephazolin and gentamicin were prescribed or continued (for group 2 patients whose infections occurred within 7 days after operation) or changed to more appropriate antibiotics based on the bacteriological sensitivities.

Operative morbidity and mortality were defined as complications and deaths occurring within 30 days after the operation or during the same hospitalization. The clinicopathological characteristics, surgical procedures and operative results of the patients were compared between the two groups. Continuous variables were expressed as mean(s.d.) and were compared using Student's *t* test. Frequencies were compared with the χ^2 test. $P<0·05$ was considered significant.

Results

Background characteristics of the patients

The indications for liver resection and background patient characteristics are shown in *Table 1*. There were no significant differences in tumour pathology or any demographic category between the two groups.

Surgical procedures and intraoperative results

There were no significant differences in any category between the two groups (*Table 2*). Only one patient in group 1 and four in group 2 did not require the hepatic

inflow blood occlusion technique. Mean(s.d.) total liver ischaemic time did not differ significantly between the two groups (44·8(26·4) min in group 1 *versus* 41·2(26·5) min in group 2; $t = 0·75$, 120 d.f., $P = 0·46$).

Postoperative course

Postoperative complications occurred in 16 patients in each group ($\chi^2 = 0·02$, 1 d.f., $P = 0·88$). Infective complications occurred in 14 (23 per cent) group 1 patients (consisting of two central venous catheter infections, three urinary infections, two wound infections, three pulmonary infections, five intra-abdominal absesses and one case of parotitis) and 15 (23 per cent) group 2 patients (one central venous catheter infection, five urinary infections, one wound infection, one pulmonary infection and eight intra-abdominal abscesses). Bile leakage developed in three group 1 and five group 2 patients, and caused intra-abdominal abscess in four patients (two in each group). Of the patients with intra-abdominal abscess, ten (four in group 1 and six in group 2) required percutaneous catheter drainage[6,10]. The remaining patients were treated by intraoperative placement of drainage tubes. All patients with bile leakage recovered completely within 1·5 months of operation. Wound dehiscence developed in one patient in group 2 following infection and required repair.

Non-infective complications occurred in five group 1 patients (consisting of one patient with prolonged jaundice, two with ascites and two with pleural effusions) and three group 2 patients (two with ascites and one with a pleural effusion). One patient had bile leakage and prolonged jaundice for 3 weeks and healed spontaneously. There were no significant differences between the groups with respect to the infective ($P = 0·95$) and non-infective ($P = 0·49$) complication rates. No patient in either group died after hepatectomy.

Bacteriology and antibiotic usage

Staphylococcus aureus was the most frequently cultured micro-organism (seven in group 1, five in group 2), with five (one in group 1, four in group 2) being methicillin resistant. The other bacterial isolates included *Candida* in eight patients (three in group 1, five in group 2), *Klebsiella* in four (three in group 1, one in group 2), *Streptococcus* in five (three in group 1, two in group 2), *Escherichia coli* in three (one in group 1, two in group 2), *Pseudomonas* in three (one in group 1, two in group 2), *Proteus* in three (two in group 1, one in group 2), *Veillonella* in one (group 1), *Acinetobacter* in one (group 1) and *Staphylococcus epidermidis* in one (group 2). Bacteraemia developed in two patients with intra-abdominal abscess (*Klebsiella* in group 1 and *Candida* in group 2).

Of the 14 group 1 patients with infective complications, 11 required antibiotic therapy. Two patients with urinary infection and one patient with a central venous catheter infection did not need antibiotics as the septic symptoms were immediately relieved by removal of the infected catheter. A total of 51 group 1 patients (82 per cent) did not receive any systemic antibiotics during the entire course. Of the group 2 patients with infective complications, a change of antibiotics was required in 11 patients as the prescribed antibiotics were ineffective.

There were no side-effects from the antibiotics used in this study. Although the mean(s.d.) postoperative hospital stay did not differ significantly between the two groups (13·0(7·5) days for group 1 *versus* 14·5(7·8) days for group 2; $t = -1·17$, 125 d.f., $P = 0·24$), the mean(s.d.) total hospital costs in group 2 were significantly higher (US\$7494(3564) *versus* US\$9185(5363); $t = -3·72$, 112 d.f., $P < 0·001$).

Discussion

As liver resection has been associated with a high rate of susceptibility to infection, many authors have proposed potential factors that may lead to an increase in infection rate in such patients[3–7,11,14,22]. These factors include the presence of diabetes mellitus, cirrhosis, chronic pulmonary disease, surgical extension to the thorax, previous liver surgery, wide extent of resection, long operating time and a large volume of operative blood loss[3–7,11,14]. However, there were no significant differences between the present two groups with respect to the above factors. Therefore, using the same postoperative management, the operative results of both groups were comparable.

Antibiotic prophylaxis for infective complications after elective non-contaminated surgery is generally not necessary[8,9]. However, recent controlled studies suggest that prophylactic antibiotics may provide benefits to some high-risk patients undergoing simple and clean procedures[20,21] or elective biliary surgery[18].

In this study, to avoid any bias of surgical decision-making during the operation, randomization was performed following operation and systemic antibiotics were not used before surgery. Theoretically, such antibiotics had no prophylactic effect on infective complications. However, the authors used a recommended preoperative protocol of bowel preparation and oral antibiotics[9], as a considerable serum level of erythromycin during operation may play some role in reducing the perioperative infection rate[9]. This study was performed to evaluate the effectiveness of systemic antibiotics for the prevention of posthepatectomy infection.

Infective complications occurred at similar rates in both groups. Some of the infective complications were related to operative technique (such as wound infection or intra-abdominal abscess). As good antibiotics cannot cover a bad surgery[8,9], postoperative systemic antibiotics cannot prevent such infections. Although the antibiotics in this study were selected for their high biliary secretion, septic symptoms still developed in patients with biliary leakage, and some patients required a change of antibiotics. Moreover, postoperative antibiotics were also unable to prevent technique-unrelated infections (such as respiratory or urinary tract infection, central venous catheter sepsis or parotitis).

In this study, no patient showed adverse side-effects from the selected antibiotics. However, the incidence of so-called 'opportunistic nosocomial infections'[8,9,22], such as fungal and methicillin-resistant *S. aureus* infections, was higher in group 2 patients, although the difference was not statistically significant. Such micro-organisms are resistant to generally used antibiotics and thus other more expensive antibiotics may be required[8,9,22]. In this study, the hospital costs were higher in group 2 patients than in group 1 patients, even though the length of hospital stay was similar in both groups.

As a result of the widely accepted use of antibiotic prophylaxis after liver resection[3–7,9,22], the possibility of performing hepatectomy without systemic antibiotic coverage has never been reported. With a reduction in operative bleeding, preservation of functioning liver[15], careful postoperative observation and early treatment of infective complications, it was found that some minor infections could be cured without antibiotics. Thus, more than 80 per cent of group 1 patients, even those with high-risk factors, could tolerate hepatectomy without needing systemic antibiotics.

Bacteraemia occurred in two patients with intra-abdominal abscess in this series. This condition can be fatal if not treated in time[5–7]. Because diagnosis of intra-abdominal abscess after hepatectomy is difficult[6], when septic symptoms occur after hepatectomy, and other possible sites of infection are not discovered, prompt imaging studies such as abdominal ultrasonography or CT should be performed, rather than prescribing antibiotics[6,7,10]. Moreover, avoidance of posthepatectomy infections, by early removal of the monitoring catheters, fine dissection of liver parenchyma, reduction of devitalized tissue in dead spaces, and careful haemostasis and closing of the transected tiny bile ducts during hepatectomy, is more important than the use of antibiotics.

It is concluded that most patients tolerate liver resection without systemic antibiotics. Routine use of antibiotics after elective liver resection is both unnecessary and costly. Antibiotics cannot prevent postoperative infections, and their use can be delayed until infective complications occur.

Acknowledgements

The authors thank Professor M. Makuuchi, Second Department of Surgery, Faculty of Medicine, University of Tokyo, Tokyo, Japan, for his suggestion of this manuscript, and Ms F. L. Kuo for statistical assistance. This work has been supported in part by grant nos TVGH 844601, 854601 and NSC 83-0412-B-075A-013.

Encouraging results of split-liver transplantation

D. F. MIRZA, O. ACHILLEOS, J. PIRENNE, J. A. C. BUCKELS, P. McMASTER and A. D. MAYER

Liver and Hepatobiliary Unit, Queen Elizabeth Hospital, Edgbaston, Birmingham B15 2TH, UK
Correspondence to: Mr *A. D. Mayer*

Background Liver donor shortage presently accounts for a 10 per cent waiting list mortality rate. Split-liver transplantation (SLT) can improve utilization of this scarce resource.

Methods Twenty-four SLTs (11 left, 13 right grafts) from 13 livers were performed in 23 patients (nine adults, 14 children), comprising 4·5 per cent of all orthotopic liver transplants (14 urgent or emergency, ten elective). The left graft comprised segments II and III, whereas the right graft comprised segments V–VIII in eight cases, IV–VIII in three, and segments I, IV–VIII, and I, V–VIII in one case each. Additional arterial extension grafts were required in six of 24 cases, and portal venous interposition graft in one.

Results Twenty-one grafts showed good initial function, with one primary non-function and two initial poor function. The median peak aspartate aminotransferase level was 782 (range 94–2301) and 982 (range 382–2520) units/l for left and right grafts respectively. Five patients died (all urgent recipients), all within the first 30 days after surgery. Two SLT recipients underwent subsequent retransplantation. All ten elective recipients are alive. The 1-year actuarial patient and graft survival rates at a median follow-up of 20 months were 78 and 68 per cent respectively.

Conclusion These encouraging results compare favourably with those of reduced-size and whole-liver transplantation and justify wider application of this technique, thereby optimizing donor resource use.

The shortage of livers from cadaveric donors is the main factor preventing growth in liver transplantation programmes. The introduction of reduced-size liver transplantation (RLT), where only part of a liver is transplanted, has improved the availability for paediatric recipients[1-3]. Living related liver transplantation (LRT) has also had a favourable impact on paediatric transplantation in several countries[4-6]. However, LRT is not applicable to most adult recipients. These innovative techniques have reduced waiting time and mortality in children, particularly in those less than 1 year old or weighing less than 10 kg[1,2]. The success of orthotopic liver transplantation (OLT), with most centres reporting survival rates of over 80 per cent after transplantation, has resulted in a relaxation of the selection criteria, leading to larger waiting lists with more debilitated potential recipients. Consequently, waiting list mortality has increased and approximately 10 per cent of patients die before a suitable organ becomes available[6-8].

In split-liver transplantation (SLT), two grafts are obtained from a single cadaveric donor liver. The left lateral segment (segments II and III) is transplanted into a paediatric recipient and the right hemiliver into an adult or larger paediatric recipient[9-12]. This results in increased paediatric organ availability without compromising the adult donor pool[3,8,13]. The early experience of SLT involved its application in extreme clinical situations with an outcome inferior to established techniques of whole OLT and RLT[3,8-12]. This paper evaluates SLT in Birmingham, UK: the logistical problems associated with SLT, surgical techniques, complications, and patient and graft outcome.

Patients and methods

Between November 1992 and April 1996, 486 patients (390 adults, 96 children) underwent 535 OLTs (427 adults, 108 children). These included 24 SLTs (4·5 per cent of OLTs) from 13 donor livers carried out in 23 patients. Two livers were split at another liver unit where the left grafts were retained. The recipient demographic details were as follows: nine adults (six women, ten grafts, median age 49 (range 25–60) years); 14 children (nine girls, median age 2 years (range 9 months to 11 years)). Fourteen of 24 grafts were carried out as urgent ($n = 11$, hospital-bound patients or in intensive care) or super-urgent ($n = 3$, acute liver failure) transplants, equivalent to United Network for Organ Sharing (UNOS) status 1 or 2, with ten carried out in elective (UNOS 3 or 4) recipients (*Table 1*). All transplants were carried out as sequential procedures with a median cold ischaemia time (CIT) of 603 (range 435–921) min for the first graft and 102 (range 870–1326) min for the second. Immunosuppression was based on triple drug therapy with cyclosporin, azathioprine and steroids with an aim to stop steroids at 3 months[14,15].

Donor details

Median donor age was 21 (range 7–42) years; blood group, O ($n = 9$), B ($n = 3$) and A ($n = 1$); median weight 67 (range 22–100) kg. The cause of death was trauma in six, intracranial bleed in four and 'other' in three (hypoxia following status asthmaticus, hydrocephalus, cerebral infarction). All donors were ABO identical and preserved with University of Wisconsin solution. Iliac vessels were retrieved to be used as extension grafts if necessary. Arterial anatomy was anomalous in three of 13 cases: right hepatic from superior mesenteric artery ($n = 2$) and left hepatic from left gastric artery ($n = 1$).

Presented in part to the British Transplantation Society, London, UK, October 1995, and the American Association for the Study of Liver Diseases, Chicago, USA, November 1996, and published in abstract form as *Hepatology* 1996; **24**(Suppl): 302
Paper accepted 20 June 1997

Table 1 Indications for split-liver transplantation in adults and children

Adults	
Primary grafts	
Primary biliary cirrhosis	3
Non-A, non-B hepatitis	2
Primary sclerosing cholangitis	1
Wilson's disease	1
Hepatitis C	1
Alcohol	1
Regrafts	
Hepatic artery thrombosis	1
Children	
Primary grafts	
Biliary atresia	5
Biliary hypoplasia	1
Hepatoblastoma	1
Chronic active hepatitis	1
Propionic acidaemia	1
Methylmalonyl acidaemia	1
Hepatitis A	1
Regrafts	
Chronic rejection	2
Hepatic artery thrombosis	1

Bench splitting procedure, vascular and biliary reconstruction

Cholangiography to delineate segmental biliary anatomy was carried out before splitting and showed conventional bifurcation of left and right ducts in 11 livers, an immediate bifurcation of the right duct into segment VI, VII and segment V, VIII ducts amounting to a 'trifurcation', and drainage of the segment VI, VII duct into the left duct as the other anomaly. Arteriography was not performed as arterial variations were identified during the hilar dissection. The main hepatic arterial trunk was retained with the left graft in eight livers and the right graft in five. Arterial interposition grafts were required in six SLTs: three left and three right grafts. In the remaining 18 patients no extension grafts were used as the recipient artery was anastomosed directly to the donor vessel as follows. (1) Left graft: donor hepatic trunk in five, donor left hepatic artery in three; and (2) right graft: donor hepatic trunk in five, donor right hepatic artery in three and the replaced right hepatic from superior mesenteric artery in two. The three donor hepatic arterial anomalies facilitated splitting and both grafts were prepared with an adequate donor artery. All arterial anastomoses were carried out using magnification loupes. The main portal trunk was retained with the left graft in 11 livers and the right graft in two. Only one donor iliac vein interposition graft was used (the first SLT) from the recipient portal vein to the donor left portal vein. In 23 of 24 SLTs the recipient vein was anastomosed directly to the donor right portal vein ($n = 11$), main vein ($n = 11$; nine left, two right grafts) or left vein ($n = 1$).

A blunt lachrymal probe was then passed up to the biliary bifurcation and the left duct divided, always retaining the common duct with the right graft. Biliary reconstruction was as follows: left duct to jejunal Roux loop for all 11 left grafts; duct-to-duct anastomosis in eight (one with a T tube), and a main duct to jejunal Roux loop in five of the 13 right grafts. The donor main duct was shortened until satisfactory bleeding was observed before commencing the biliary anastomosis, carried out with 5/0 polydioxanone (PDS; Ethicon, Edinburgh, UK). The left hepatic vein was divided at its junction with the inferior vena cava (IVC), the IVC oversewn and retained with the right graft. The parenchymal hepatic division was carried out by haemostat dissection and bipolar diathermy, carefully ligating all biliary and vascular branches. The cut surface was then sprayed with fibrin glue (Tisseal; Immuno, Vienna, Austria). There were 11 left grafts (segments II and III) transplanted into nine children and two adults; and 13 right grafts comprising segments V–VIII in eight; IV–VIII in three; I, IV–VIII and I, V–VIII in one patient each, transplanted into eight adults and five children. More recently the split procedure has been simplified to retain segments I and/or IV whenever possible, thereby limiting the parenchymal division phase.

The following factors were studied: early graft function, perioperative complications, patient morbidity, mortality, and graft and patient survival. Statistical analyses were carried out using Fisher's exact test, and survival was calculated with the Kaplan–Meier method.

Results

Perioperative complications, graft function and outcome

Of 24 SLTs, 21 showed good initial function. There was one primary graft non-function (PNF) (defined as non-life-sustaining graft function resulting in death or retransplantation within the first week), and two with initial dysfunction (poor early graft function with prolonged intensive care stay, peak aspartate aminotransferase (ASAT) level more than 2000 units/l, prothrombin time of over 16 s for days 2–7 after OLT). Median peak day 1–5 ASAT concentration was 782 (range 94–2301) and 982 (range 382–2520) units/l for left and right grafts respectively. There were five deaths, all in urgent or super-urgent recipients (three children, two adults; three right grafts, two left grafts; one first recipient with shorter CIT, four second recipients with longer CIT; P not significant), within the first 30 days. Causes of death were: PNF, non-thrombotic graft infarction, metabolic crisis in a child transplanted for methylmalonyl acidaemia, intracranial bleed and respiratory sepsis. The first two patients died before a suitable replacement graft could be found. Two patients having SLT underwent retransplantation for hepatic artery thrombosis (HAT) (at 3 weeks) and chronic rejection (at 7 months). Other complications recorded were relaparotomy for bleeding ($n = 1$), perihepatic haematoma ($n = 1$), pulmonary sepsis ($n = 2$), technical splenectomy ($n = 1$), anastomotic biliary stricture ($n = 2$, treated by biliary reconstruction) and a bile leak from the cut surface with an anastomotic stricture treated by pigtail catheter drainage, anastomotic dilatation and internal–external biliary drainage in one patient.

The left lateral segment was transplanted into an adult recipient twice (both small women, recipient weights 43 and 60 kg, donor weights 85 and 100 kg respectively). The first showed satisfactory initial function, but developed acute rejection and hepatic insufficiency during the second week after SLT and died from multiple organ failure secondary to non-thrombotic graft infarction before a replacement graft could be found. The second patient received this as an emergency regraft for HAT 16 days after a right SLT, with the left lateral segment weighing 760 g. All ten elective recipients are alive, one having undergone a second SLT for HAT. Median follow-up was 20 (range 8–48) months. The overall 1-year actuarial patient and graft survival rates were 78 and 68 per cent respectively.

Discussion

The innovative techniques of RLT and LRT have significantly improved organ availability in children with a reduction in mortality on waiting lists from about 15 to 5 per cent[1–3,8]. RLT, however, results in diversion of organs from the adult to the paediatric recipient pool. Donor criteria have been relaxed and many centres accept a significant proportion of marginal-quality donor livers[17,18]. One way of increasing the donor pool would be to make wider use of SLT, without diversion of organs from the adult to the paediatric pool. The early experience involved application of a new procedure in high-risk patients, often as a desperate measure, and this was reflected in a high morbidity rate[9–12]. SLT results have improved with experience and standardization of techniques[8,13,19,20], and the overall 1-year patient and graft survival rates (78 and 68 per cent respectively) for this series with a high proportion of high-risk patients compares favourably with RLT and whole OLT, and are superior (100 per cent (ten of ten patients) survival rate) in elective low-risk patients. The Paris[19] and Hamburg[20] groups have also recently shown improved results in elective recipients, underlying the importance of recipient selection. Donor selection is crucial and marginal donors, as previously defined, were not considered for SLT[17]. As regards technical details, in most instances the main portal venous and arterial trunks are allocated to the left graft, and the IVC and main bile duct always to the right graft. By dividing recipient vessels high in the hilum, the use of vascular extension grafts is minimized and only seven such extension grafts were needed (one venous, six arterial). Rat *et al.*[21] suggest allocation of the main portal vein to the right graft on the basis of an anatomical study of livers taken at post-mortem examination. However, as the left graft is implanted into a paediatric recipient, where the recipient portal vein often needs to be dissected back, the extra length of the main donor vein is essential to provide adequate length. For the right graft the donor right portal vein is anastomosed to the recipient vein.

There was only one case of HAT and the patient underwent retransplantation. This compares favourably with the incidence of vascular thrombosis following RLT and whole OLT[22–24]. Biliary complications were seen in three of the 24 patients. Necrosis of the main bile duct was not seen in cases where the main hepatic arterial trunk was retained with the left graft. All left grafts had a single-lumen left duct anastomosed to a jejunal Roux loop. The incidence of double left ducts is higher with *in situ* SLT where the left duct is divided at a level just to the right of the falciform ligament[20,25,26]. Bench cholangiography was helpful in delineating segmental bile duct anatomy; it identified two anatomical variations, and is an important step before proceeding with splitting. The bench split can be simplified by retaining segments I and IV with the right graft. Both these segments derive their arterial and portal venous perfusion from both the right and left branches. Segment I perfused well in both cases where it was retained, although a strip of hypoperfusion along the cut edge of segment IV was seen in two of four cases where segment IV was retained. This did not influence graft outcome.

There are several logistical aspects that need to be taken into consideration before SLT is set up. Close coordination between the donor, splitting and recipient teams is essential, to minimize CIT. In the authors' unit it is not yet possible to carry out two grafts simultaneously, and all SLTs were carried out sequentially; this did result in longer CIT for the second grafts. A majority of the recipients were either high risk or super-urgent (UNOS 1 or 2), and most of the early experience involved transplanting two high-risk recipients. The present approach is to select one high-risk and one elective recipient, if possible, to minimize pressure on theatre and intensive treatment unit resources.

Four of the five patients (*P* not significant) who died received the second graft of the split, although only one of these deaths was a result of poor graft function. Several approaches have been adopted to minimize CITs. Others are increasingly adopting *in situ* splitting at the donor hospital, where the left lateral segment is resected before the aorta is clamped and donor perfusion commenced, in an attempt to decrease CIT and promote organ sharing[20,24,25]. Most donor hospital theatres are not equipped for such a procedure, which adds up to 2 h to the length of the retrieval operation, and does delay cardiac and renal teams. This is one advantage of the *ex situ* split compared with *in situ* splitting. The sharing of SLTs between units reduces CITs, and this is being practised increasingly by many European centres[19,20]. Earlier SLT experience suggested that the right graft is potentially compromised compared with a whole graft, with a higher chance of surgical complications. Both left and right grafts in this series were of equal quality, with no difference in outcome. In two instances the left lateral segment was transplanted into an adult recipient. One concern in this situation is that, if there is some degree of initial dysfunction and/or the patient experiences an acute rejection episode, hepatic insufficiency may develop.

In conclusion, the results of SLT compare favourably with those of reduced- and whole-liver transplantation. Standardization of surgical techniques, careful selection of donors and recipients, and measures to reduce CIT such as increased sharing will permit its wider application, resulting in better use of the limited donor liver pool.

Background Carcinoma located in the uncinate process (CUP) of the pancreatic head is considered to be rare. Exact epidemiological data, however, are not available because the series published so far consist of fewer than ten patients. The purpose of this prospective study was to evaluate the clinical appearance of CUP and to compare findings with those of patients with carcinoma in the ventral aspect of the pancreatic head (VPC), which represents the most frequent localization.

Results Some 39 (8 per cent) of 506 evaluated patients suffered from CUP. Mean age was 63·3 years. The most frequent complaints were upper abdominal pain ($n = 32$) and weight loss ($n = 35$). Jaundice was seen in only five patients and was never an early symptom. The level of CA19-9 was raised in 33 patients. The best diagnostic procedure to detect CUP was computed tomography (CT) (sensitivity 93 per cent), whereas endoscopic retrograde cholangiopancreatography was not useful (sensitivity 21 per cent). Vascular involvement was significantly ($P < 0·01$) more common in CUP ($n = 19$) than in VPC (48 *versus* 19 per cent). This finding and the fact that most patients with CUP were diagnosed at a late stage with distant metastasis or severe vascular involvement present ($n = 21$) are responsible for the significantly lower rate of operation ($n = 25$) (64 *versus* 92 per cent, $P < 0·05$) and the significantly shorter median survival time (5 *versus* 11 months, $P < 0·05$).

Conclusion Patients with CUP have a poor prognosis as a result of the lack of early symptoms (jaundice) and early vascular involvement due to the proximity of the uncinate process to the mesenteric root. A raised level of CA19-9, together with weight loss and/or upper abdominal pain, should prompt CT.

The uncinate process arises from the embryological dorsal aspect of the pancreas. Anatomically it represents a hook-like extension of the lower part of the pancreatic head It is located just posterior to the superior mesenteric vessels along the upper border of the third portion of the duodenum. Its different embryological origin, apart from the larger ventral aspect of the pancreas, is reflected in the absence of endocrine activity due to lack of islets of Langerhans, thus resulting in a different histological appearance. The development of a malignancy within this pancreatic region is considered to be rare, but exact epidemiological data are not available.

Few authors have reported the clinicopathological findings associated with a pancreatic neoplasm arising in this area. These reports have been based on a limited number of patients: Suzuki *et al.*[1] reported on six patients and Yamaguchi[2] described three. The purpose of this study was therefore: (1) to evaluate the clinical appearance of carcinoma within the uncinate process (CUP) in a larger series of patients and to compare the findings with those in patients suffering from carcinoma within the ventral aspect of the pancreatic head (VPC); and (2) to assess the impact of modern imaging procedures and surgical techniques on outcome in these patients.

Patients and methods

This prospective study included data on 506 patients admitted to this department between 1982 and 1994 because of pancreatic malignancy. The patient's history, symptoms, validity of all diagnostic measures, therapy and outcome were recorded and entered into a database. The study included only patients who had a complete diagnostic assessment, which consisted of transcutaneous ultrasonography, contrast-enhanced computed tomography (CT), endoscopic retrograde cholangiopancreatography (ERCP), and angiography of the coeliac trunk, superior mesenteric artery and venous portal system.

CUP was defined as a pancreatic tumour localized within the uncinate process (i.e. dorsal aspect) as determined by intraoperative and/or localization data provided by the applied imaging systems.

To detect significant differences in symptomatology, and in the value of diagnostic measures as well as therapy and outcome, these parameters were compared between the two groups of patients (CUP *versus* VPC) applying χ^2 and Student's t tests. $P < 0·05$ was considered statistically significant.

Results

Some 39 (8 per cent) of 506 patients (21 men) suffered from carcinoma of the pancreatic head located in the uncinate process. Mean age was 63·3 (range 48–79) years.

Symptoms

The main complaint was upper abdominal pain especially after meals in 32 patients and weight loss exceeding 10 per cent of original body-weight in 34 (*Table 1*). The median interval between the onset of these first symptoms and confirmation of the disease was significantly longer in patients suffering from CUP than in those with VPC. Most patients ($n = 24$) had consulted a physician within this period. Frequently the primary diagnosis was thought

Table 1 Main symptoms of patients with carcinoma of the uncinate process or of the ventral pancreatic head

Symptom	CUP ($n=39$)	VPC ($n=465$)	P
Weight loss	34	316 (68)	n.s.
Abdominal pain	32	320 (69)	n.s.
Jaundice	5	334 (72)	<0·001*
Diarrhoea	24	288 (62)	n.s.
Nausea	20	195 (42)	n.s.
Interval between onset of symptoms and diagnosis (weeks)	22	10	<0·05†

Values in parentheses are percentages. CUP, carcinoma of the uncinate process; VPC, carcinoma of the ventral pancreatic head; n.s., not significant. *χ^2 test, †Student's t test

to be various forms of gastroduodenitis and/or gastroduodenal ulcer ($n=21$) and the patients were treated accordingly. The correct diagnosis was not established until second-line imaging procedures, such as CT or ERCP, were employed.

Jaundice was seen in only five patients with CUP and was never observed as an early symptom.

Laboratory findings

On admission to hospital no specific alterations in laboratory parameters were observed except for anaemia in 12 of the 39 patients and raised liver enzyme levels in eight. The tumour marker CA19-9 was raised in 33 of the 39 patients with CUP, with a mean value of 462 (range from 14 to more than 4000) units/ml (normal value 37 units/ml or less). Due to the lack of jaundice in patients with CUP, false-positive values due to raised serum bilirubin levels were not found in this series (specificity 96 per cent).

Imaging techniques

CT revealed a mass in the uncinate process in 36 of the 39 patients (*Table 2*). Three patients presented pathological CT findings, leading to the suspicion of a pancreatic anomaly within the pancreatic head; the diagnosis of CUP, however, was confirmed during laparotomy.

Transcutaneous ultrasonography was able to detect enlargement of the uncinate process in 26 patients. In VPC the sensitivity of this method was significantly higher (67 *versus* 89 per cent, $P<0\cdot01$).

Pathological findings on ERCP were obstruction or stenosis of the main pancreatic duct in five patients; three patients had stenosis of the common bile duct and one had infiltration of the duodenal mucosa. The sensitivity of ERCP in patients with VPC was significantly higher, being the only single technique reaching a sensitivity and specificity of over 90 per cent (21 *versus* 92 per cent in VPC, $P<0\cdot001$).

Table 2 Sensitivity and specificity of diagnostic procedures in carcinoma of the uncinate process

Diagnostic procedure	Sensitivity (%)	Specificity (%)	P*
Transcutaneous ultrasonography	62	78	<0·05
ERCP	21	92	<0·001
Computed tomography	93	88	n.s.
Estimation of CA19-9 level	84	96	n.s.

ERCP, endoscopic retrograde cholangiopancreatography; n.s., not significant. *Carcinoma of the uncinate process *versus* carcinoma of the ventral pancreatic head (χ^2 test)

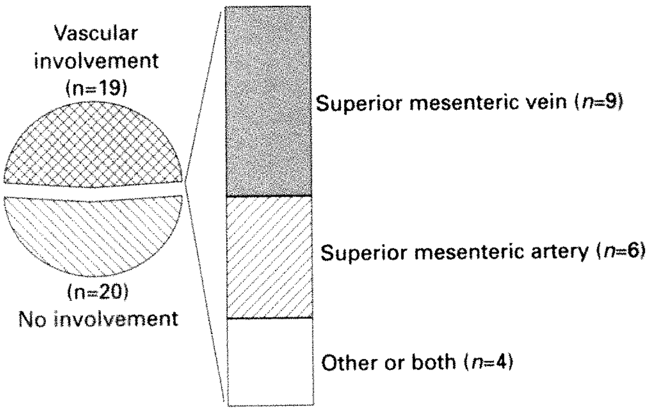

Fig. 1 Vascular involvement: incidence and localization

Angiography revealed encasement or occlusion of a major vessel in 19 patients with CUP (*Fig. 1, Table 3*), significantly more often than in VPC (19 of 39 *versus* 88 of 465, $P<0\cdot001$).

Therapy

Only 24 patients were considered primarily as candidates for operation. Ten patients presented with liver metastases at the time of diagnosis. In the absence of jaundice and/or duodenal obstruction, no immediate surgical palliation was necessary and these patients received systemic chemotherapy ($n=4$; 5-fluorouracil 2250 mg per m^2 per week), or no therapy at all if the general condition did not allow such treatment or the patient did not consent.

Angiography showed occlusion of the superior mesenteric vein and/or artery in four patients. These patients were therefore considered to suffer from an irresectable tumour and received either systemic chemotherapy in the above-mentioned protocol ($n=2$) or, after its introduction in 1992, regional chemotherapy via a coeliac trunk catheter[4].

In 12 patients resection of the tumour was performed (eight pylorus-preserving partial pancreaticoduodenectomies, four standard partial pancreaticoduodenectomies). In four of these cases the surgeon considered the operation as palliative, i.e. an R_2 resection (macroscopically residual tumour remaining according to the tumour node metastasis classification). In two patients

Table 3 Venous vascular involvement (Ishikawa classification[3]) in carcinoma of the uncinate process

Stage	Description	No. of patients ($n=30$)
I	Normal	15
II	Smooth shift	2
III	Unilateral narrowing	2
IV	Bilateral narrowing	4
V	Bilateral narrowing with collateral vein	7

involved venous segments were resected and an end-to-end anastomosis was performed; in one patient an allograft replaced the resected portal vein. Six patients underwent a bypass operation: three Billroth II resections, two choledochojejunostomies, one double bypass (Billroth II with choledochojejunostomy). Seven patients underwent exploratory laparotomy without resection or bypass, due to local irresectability ($n = 5$) or the presence of distant metastases ($n = 2$).

Major complications were seen in two patients (one anastomotic leak, one postoperative bleed); neither required reoperation. Conservatively treated minor complications were prolonged gastric emptying ($n = 2$), superficial wound infection ($n = 1$) and haematuria following intraoperative placement of a percutaneous urinary catheter ($n = 2$).

Lymph node involvement

In 12 patients in whom resection of the tumour was achieved, a complete pathological investigation was performed. In ten cases a grade II tumour was seen, in one case a grade II-III tumour and in one a grade III tumour. None of these patients was free from lymph node metastasis. The most frequent location of involved nodes was adjacent to the superior mesenteric artery and vein ($n = 7$) and the small bowel mesentery ($n = 5$).

Outcome

The median survival time after the diagnosis of CUP was 5 (range 0–11) months. This is significantly shorter than for patients with VPC (11 months) ($P < 0{\cdot}05$). The bypass group had a median survival of 5 months. When no surgical option was available ($n = 21$), median survival was 4 months (*Table 4*).

Discussion

Pancreatic carcinoma within the uncinate process is rare. In smaller previously published series Yamaguchi[2] reported an incidence of 2·5 per cent (three of 119 patients), and Suzuki *et al.*[1] found an incidence of 11 per cent (six of 56). In the present series, 39 (8 per cent) of 506 patients suffered from CUP.

The description of a rare anatomical localization for pancreatic cancer alone might be of statistical interest only. However, the authors believe that a more accurate classification than that simply of cancer of the pancreatic head, body or tail is necessary to allow proper assessment of the disease, especially if neoplasm at a rare site is accompanied by an unusual clinical appearance requiring an alternative strategy in diagnosis and therapy.

Patients with CUP in this study exhibited a few non-specific symptoms, weight loss and inconstant upper abdominal pain being the leading ones. Therefore, these patients were usually misdiagnosed on their first medical examination, a phenomenon recognized in patients with pancreatic cancer[5]. Concomitantly the time between first medical consultation and establishment of the correct diagnoses took significantly longer in patients with CUP. This seems to be due not only to the lack of specific early symptoms, especially jaundice as the cardinal symptom in the 'classical' location, but also to additional difficulties in the application of imaging techniques.

Transcutaneous ultrasonography, as the first-line imaging technique for the diagnosis of abdominal disorders, has an overall sensitivity of 70–80 per cent in pancreatic cancer[6]. Imaging of the uncinate process, however, may be hindered by overlying bowel. The embryologically dorsal aspect of the pancreas representing the uncinate process also frequently exhibits hypo-echogenicity due to different fat content[7], a fact that impairs the localization of a tumour in this area.

In the authors' experience the easily available tumour marker CA19-9 is a valuable diagnostic method with a sensitivity and specificity of more than 80 per cent[8]. Eighty-four per cent of patients investigated exhibited pathological levels greater than 37 units/ml with a specificity of 96 per cent.

CT proved to be the best diagnostic tool with a sensitivity of 93 per cent. Smaller masses in the uncinate process were detected by CT, when other techniques showed normal morphology. Unfortunately CT examinations are costly and have the disadvantage of irradiation.

ERCP is the only single imaging technique with a specificity greater than 90 per cent in detecting pancreatic cancer[5,9]. In contrast, abnormalities of the common bile duct and/or the pancreatic duct are very rare in CUP, owing to the distance of the uncinate process from these structures. Therefore ERCP is of little or no use in detecting CUP.

Before the widespread availability of CT, angiography was considered a reliable method for detecting CUP[1]. Today, this diagnostic tool is reserved for the assessment of resectability in pancreatic cancer. None of the present patients with CUP exhibited pathological angiographic signs without the demonstration of a tumour in the uncinate process by CT. The proximity of the uncinate process to the mesenteric root, however, explains the high frequency of vascular involvement. This anatomical relationship also explains the significantly lower resection rate of CUP, compared with VPC. Resection of involved vascular segments was necessary in three of 12 resected patients. In the authors' opinion it is therefore necessary

Table 4 Survival according to Union Internacional Contra la Cancrum stage

	CUP		Median survival (months)	
Stage	Men	Women	CUP	VPC

II	3	1	9	12
III	8	7	6	8
IV	7	13	3·5	6
All stages			5	11*

CUP, carcinoma of the uncinate process; VPC, carcinoma of the ventral pancreatic head. *$P < 0{\cdot}05$ (VPC *versus* CUP, Student's *t* test) to know whether vascular infiltration is to be expected before starting a potentially dangerous pancreatic resection, even if performed by an experienced surgeon.

It is difficult to compare the outcome of patients with CUP in the present study with the findings from earlier series, as these included only small numbers of patients, but it seems that outcome has not improved despite better diagnostic methods. The mortality rate after pancreatic resection, however, has decreased significantly over the past 20 years[10].

The prognosis of patients suffering from CUP is worse than that for other forms of pancreatic cancer. From the present study, three important factors appear to be responsible for this phenomenon: (1) the lack of specific early symptoms especially of jaundice; (2) higher demands on imaging systems; and (3) early vascular involvement resulting in irresectability. The localization of pancreatic cancer in the uncinate process therefore represents a separate entity of its own. The diagnostic demands for proper preoperative assessment are high and require experience. Even smaller tumours (which are generally accompanied by a better prognosis) directly adjacent to the mesenteric root may be considered irresectable if vascular replacement is not considered. This may be a strenuous and risky addition to the planned operation if the surgeon is inexperienced in these procedures.

The surgical therapy of CUP should therefore be undertaken only in referral centres where pancreatic resection is performed frequently.

In conclusion, patients presenting with upper abdominal discomfort and a raised serum level of CA19-9 should undergo CT without delay to exclude a pancreatic neoplasm. Owing to the lack of accurate screening methods, the only way to improve the poor prognosis of patients with pancreatic carcinoma in the uncinate process appears to be the early application of currently available diagnostic tools and the constant improvement of surgical results along with the commitment to perform extended procedures including vascular replacement.

Background Endothelin 1 (ET-1), a vasoconstrictor peptide, has been implicated as a tumour growth stimulator and an angiogenesis factor.

Methods To assess the involvement of ET-1 in colorectal cancer, immunoelectron microscopy for ET-1 was performed in colorectal liver metastases and normal liver ($n = 6$). ET-1 plasma levels were measured by radioimmunoassay in patients with colorectal cancer, with ($n = 18$) and without ($n = 12$) liver metastases, and in controls ($n = 22$).

Results In normal liver, ET-1 was present in endothelial cells; in tumour, it was observed in endothelial cells, tumour cells and myofibroblasts. Mean(s.d.) plasma ET-1 levels were 2·75 (1·37) pg/ml in controls, 4·53(1·61) pg/ml in patients with colorectal liver metastases ($P = 0·001$) and 3·92(1·32) pg/ml in patients without metastases ($P = 0·02$).

Conclusion ET-1 was present in various cell types within colorectal liver metastases and raised levels were found in the plasma of patients with colorectal cancer. ET-1 may not only modulate tumour vascular tone but also act on tumour growth and angiogenesis, both locally and systemically.

The level of endothelin 1 (ET-1), a peptide with recognized vasoconstrictor properties, is known to be raised in the plasma of patients with a variety of conditions associated with vasospasm including pregnancy-induced hypertension, myocardial infarction and cardiogenic shock[1–3]. ET-1 plasma levels are also raised in patients with hepatocellular carcinoma[4].

In addition to its vasoconstrictor properties, ET-1 stimulates cellular proliferation *in vitro* in a variety of normal cell types including smooth muscle, fibroblasts, renal mesangial cells[5–7] and several tumour cell lines, including a number derived from colorectal cancers[8]. Histochemical analysis of different types of cancer, e.g. hepatocellular carcinoma[9], showed raised levels of ET-1 in tumour compared with normal tissue. Immunohistochemical analysis on primary colorectal cancer specimens demonstrated a heterogeneous distribution of ET-1 binding sites around tumour cell nests and associated vessels[10]. These findings suggest that ET-1 may perform a paracrine function in such tumours, in relation to both mitogenesis and blood supply.

To assess the importance of ET-1 in colorectal cancer, with particular emphasis on liver metastases, immunoelectron microscopy for ET-1 was performed on colorectal liver metastases and adjacent normal liver obtained at hepatectomy. Immunoelectron microscopy was chosen, as opposed to immunohistochemistry, so that the presence of ET-1 could be detected and also the cell types associated with it identified. In addition, plasma levels of ET-1 were measured in patients with colorectal cancer, with and without liver metastases, and compared with those in an age-and sex-matched control group.

Patients and methods

Pre-embedding immunohistochemistry for electron microscopy

Patients and tissue preparation. Six patients undergoing surgery for colorectal liver metastases were included in this study; five patients (age range 56-65 years) underwent right hemihepatectomy and one patient (aged 49 years) had segments VI and VII excised from the right liver lobe. Specimens were taken from metastatic tissue and from normal liver (at least 5 cm away from the tumour) and were fixed, within 30 min of excision, in 4 per cent paraformaldehyde and 0·25 per cent glutaraldehyde in 0·1 mol/l cacodylate buffer pH 7·3 for no less than 4–6 h at 4°C[11]. Tissue was then transferred to cacodylate buffer and stored overnight at 4°C.

Pre-embedding immunohistochemistry. For localization of ET-1, tissue was processed according to the peroxidase–anti-peroxidase (PAP) method of Sternberger[12], modified as reported previously[13,14]. Briefly, samples were exposed to 0·3 per cent hydrogen peroxide in 50 per cent methanol for 30 min (for blocking endogenous peroxidase activity), washed in 0·1 mol/l Tris buffer pH 7·4 (Tris), exposed to normal goat serum (Nordic Immunology, Tilberg, The Netherlands) diluted 1:40 in Tris containing 0·1 per cent sodium azide and 0·5 per cent bovine albumin (Sigma, Poole, UK) for 1·5 h and then rinsed in Tris. Samples were incubated for 48 h at 4°C with a rabbit antibody for ET-1 or eNOS (endothelial nitric oxide synthase) at a dilution of 1:1000 in Tris containing 0·1 per cent sodium azide and 0·5 per cent bovine albumin. The specimens were washed in Tris and exposed for 1·5 h to goat antirabbit immunoglobulin G serum (Cappel Labs, West Chester, Pennsylvania, USA) diluted 1:40 in Tris containing 0·1 per cent sodium azide and 0·5 per cent bovine albumin, washed in Tris, and incubated for 3 h with rabbit PAP complex (Dakopatts, Glostrup, Denmark) diluted 1:60 in Tris. After exposure to 3′,3′-diaminobenzidine (Sigma) and hydrogen peroxide, the specimens were washed in Tris and then postfixed with 2·5 per cent glutaraldehyde in cacodylated buffer (pH 7·4) overnight. The specimens were washed with phosphate buffer, postfixed in 1 per cent osmium tetroxide, dehydrated through a graded series of ethanol and propylene oxide and then embedded in epoxy resin (Durcupan A/M; Fluka

Presented to the Surgical Research Society in Birmingham, UK, June 1996 and published in abstract form as *Br J Surg* 1996; **83**: 1628.

Paper accepted 18 September 1997

HE, Switzerland) as described previously[11], for transmission electron microscopy. Semithin sections for preliminary electron microscopy analysis were stained with 1 per cent toluidene blue and examined under a Ziess light microscope (Carl Zeiss, Jena, Germany). Ultrathin sections were stained with uranyl acetate and lead citrate, and investigated using a Jeol TEM-1010 microscope (Japan).

Assays for endothelin 1 and thrombomodulin

Blood collection. Three groups of patients were studied: controls ($n = 22$), patients with primary colorectal cancer without liver metastases ($n = 12$) and patients with liver metastases ($n = 18$). Patients with hypertension, renal failure, heart disease, pre-existing liver disease or Raynaud's phenomenon, which are independently associated with raised ET-1 levels, were excluded.

All patients had a fasting venous specimen taken before surgery; blood for thrombomodulin (TM) and ET-1 assay was collected into precooled bottles containing trisodium citrate 0·109 mol/l and ethylenediamine tetra-acetic acid 9 mmol/l respectively. TM was used as a marker of endothelial damage, as ET-1 levels are raised in the presence of endothelial trauma. The specimens were centrifuged at 1000*g* for 15 min at 4°C and the plasma was frozen at − 70°C within 1 h of collection.

Endothelin 1 radioimmunoassay. Plasma ET-1 was measured by radioimmunoassay (Nichols Institute Diagnostics, Saffron Walden, UK) according to the manufacturer's instructions. ET-1 concentrations were calculated by plotting the percentage bound against log concentrations of known standards.

Thrombomodulin assay. Plasma TM was measured by an enzyme-linked immunosorbent assay (Diagnostica Stago, Asnieres, France) according to the manufacturer's instructions. Plates were read at 492 nm and a standard curve plotted using absorbance against log concentration.

Statistical analysis. Values are mean(s.d.). The significance of the differences was calculated using paired and unpaired *t* tests. $P < 0·05$ was considered significant. Clinical information, including carcinoembryonic antigen (CEA) level, tumour load and results of liver function tests, were recorded for each patient.

Results

Immunoelectron microscopy for endothelin 1

Normal liver. Within the portal tracts, the branches of the hepatic artery and vein were lined by a single layer of endothelial cells. Only a few endothelial cells showed immunopositivity for ET-1 and, when present, the level of labelling was low compared with that in similar areas of the tumour.

Liver metastases. The colorectal liver metastases had a markedly different morphological structure. A heterogeneous distribution of blood vessels was observed throughout the tumours, with the central portions showing areas lacking any differentiation or cellular boundaries, as described previously[15]. The tumour blood vessels appeared uniformly primitive lacking both a continuous smooth muscle coat and any evidence of innervation (*Fig. 1*). The only exception to this pattern was at the junction with the adjacent liver, where presumably normal blood vessels were being incorporated into the tumour and as such still retained a degree of their normal structure. The tumour appeared markedly less vascular than the surrounding tissue. In addition, a large number of myofibroblasts and

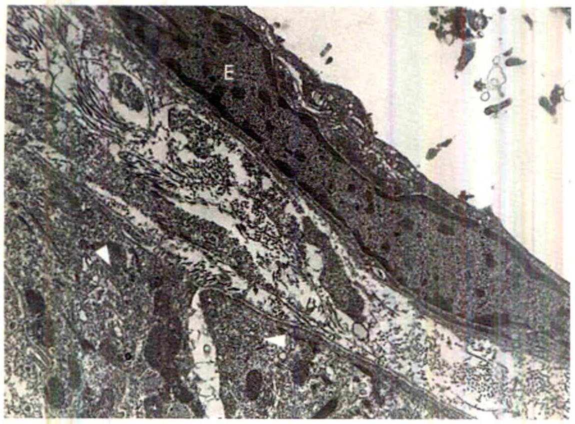

Fig. 1 Electron micrograph of a blood vessel within a liver metastasis, showing typical endothelin 1 immunostaining of an endothelial cell (E). Note the adjacent unlabelled cells (arrowheads) (original magnification × 10 000)

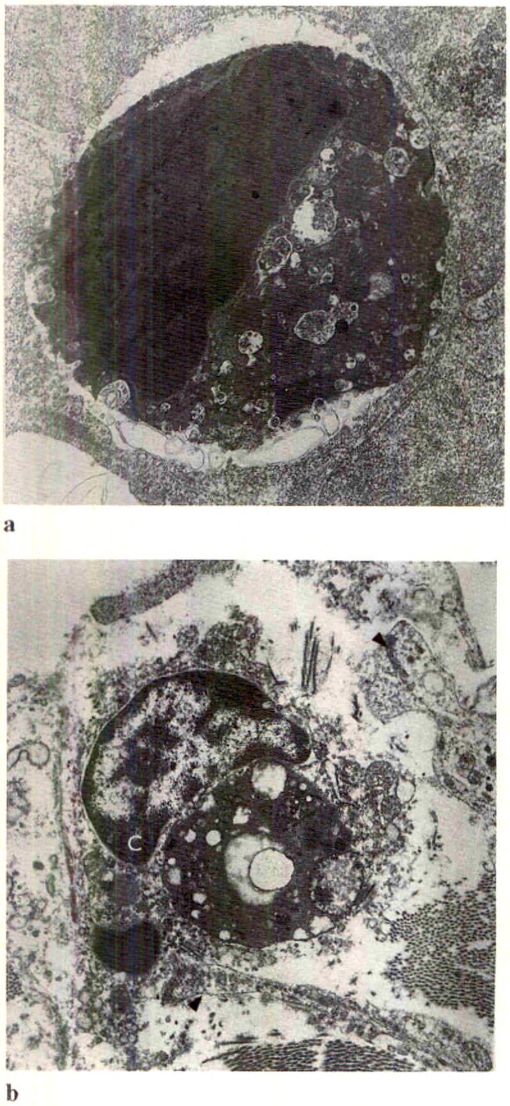

Fig. 2 a Endothelin 1-positive labelled tumour cell in metastatic tissue (original magnification × 20 000). **b** Cancer cell (C) stained positive for endothelin 1. Note the adjacent unlabelled cells (arrowheads) (original magnification × 13 000)

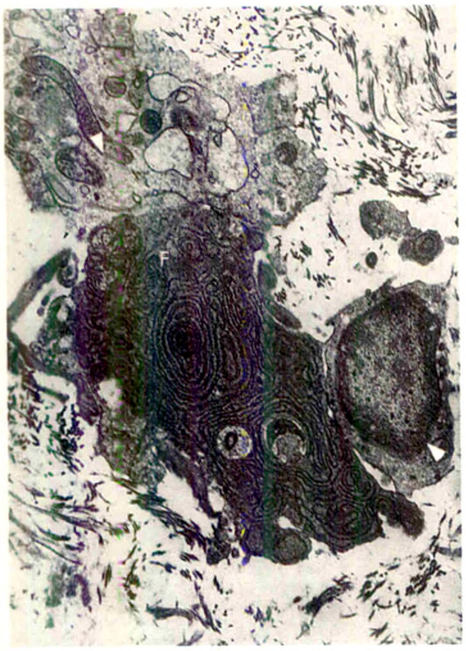

Fig. 3 Endothelin 1-positive labelled fibroblast (F) within a liver metastasis. Note the adjacent unlabelled cells (arrowheads) (original magnification × 10 000)

connective tissue were found around the tumour cell nests. The distribution of ET-1 was very different from that in normal liver with ET-1 staining strongly positive within the tumour cells (*Fig. 2*) and the surrounding fibroblasts (*Fig. 3*). In addition there was an increase in the percentage of the population of ET-1-positive endothelial cells in these tumours.

Plasma levels of endothelin 1 and thrombomodulin

Mean(s.d.) plasma level of ET-1 in the control group (age range 42–82 (mean 59·5) years; eight women and 14 men) was 2·75(1·37) pg/ml. In patients with colorectal cancer without metastases (age range 55–77 (mean 64·2) years; seven women and five men) it was 3·92(1·32) pg/ml and in those with liver metastases (age range 46–75 (mean 58·9) years; three women and 15 men) 4·53(1·61) pg/ml (*Fig. 4*). There was a significant difference between the patients with cancer and the control group ($P = 0{\cdot}001$ and $P = 0{\cdot}02$ for patients with metastases and primary cancer respectively) whilst there was no significant difference between the two groups of patients with cancer. No correlation was found between ET-1 level and liver function or serum CEA, but ET-1 concentration appeared to rise with increasing size of the liver metastases.

The mean(s.d.) TM level in the control group (53·8 (15·8) ng/ml) was not significantly different from that in the primary colorectal cancer group (52·0(11·8) ng/ml) or metastases group (64·3(22·6) ng/ml) (*Fig. 5*).

Discussion

ET-1 is known to be produced predominantly by vascular endothelial cells[16], with the precursor peptide processed to the mature form inside the cell. As well as having a local

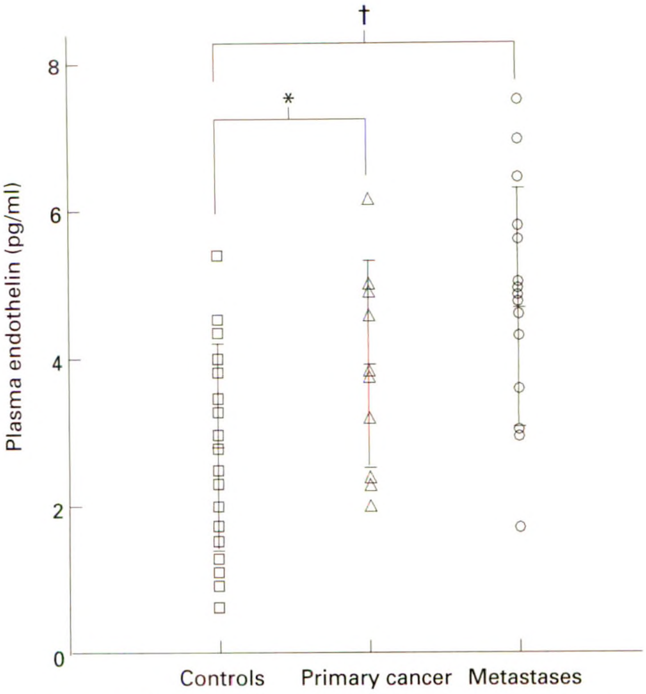

Fig. 4 Levels of endothelin-1 in plasma from patients with or without colorectal cancer. Bars are mean(s.d.). There were no significant differences between groups (unpaired *t* test)

effect, a systemic action is suggested by its presence in the plasma of healthy individuals. The results of this study suggest that a number of different cell types within colorectal liver metastases produce ET-1 with a concomitant rise in plasma levels.

The presence of ET-1 within the endothelium of normal hepatic vessels, demonstrated by immunoelectron microscopy, is in keeping with previous findings in other vascular beds, e.g. skin and coronary circulation[17,18], and conforms to the suggested function of ET-1 as an endothelial cell-derived vasoconstrictor. ET-1 is known to influence normal hepatocytes, bile flow and hepatic arterial and portal venous blood flow, with the liver also being one of the major sites of endothelin clearance[19,20]. It is not, however, a major source of ET-1 as illustrated by its absence in the remainder of the liver in this study.

Studies involving tissue culture systems have shown that a variety of tumour cell lines including colonic adenocarcinomas produce ET-1, which is then detectable in the culture medium[8]. Such findings are mirrored *in vivo* with Inagaki *et al.*[10] showing increased amounts of ET-1 in primary colonic cancers and increased levels of ET-1 receptors on surrounding cells including myofibroblasts.

A possible explanation for these findings may be found outside the commonly accepted role of endothelins as vasoconstrictors. ET-1 is known to be mitogenic for a variety of cell types including vascular smooth muscle, renal mesangial cells and colonic cancers[5-8]. Shichiri and colleagues[8] not only demonstrated that a variety of epithelial human cancer cell lines produced ET-1 but also that the peptide caused a rise in mitogenesis in a dose-dependent manner. Given the above findings in colonic cancers, ET-1 may have a paracrine or autocrine function in regard to tumour growth. In addition to its mitogenic effect, ET-1 is also directly and indirectly angiogenic, a process of particular importance in tumour growth. ET-1 is a direct endothelial cell mitogen and indirectly stimulates angiogenesis by causing monocytes to produce interleukin 8, a potent angiogenic agent[21,22].

ET-1 was present in large amounts within the cytoplasm of tumour cells and surrounding myofibroblasts throughout all the specimens examined. This raised expression suggests that ET-1 may be produced by both tumour cells and surrounding associated cell types and may therefore play a part in tumour growth regulation. The increased expression of ET-1 in tumour vessel endothelial cells compared with normal hepatic vasculature, demonstrated using immunospecific peroxidase, may suggest an upregulation of its vasoconstrictor effect in addition to growth stimulation.

The increase in production of ET-1 by colonic cancers is mirrored in the plasma of such patients, suggesting a systemic as well as a local function. It is recognized that primary tumours may influence not only their own growth but also that of distant metastases[23]. This appears to be achieved via the release of a variety of regulatory angiogenic and mitogenic substances[24]. ET-1 may perform a function in this regard with increased production perhaps leading to greater metastatic growth. The use of ET-1 as a tumour marker, however, is unlikely to be of any clinical use given the degree of overlap in the three groups of patients studied and the number of other conditions independently associated with an increased ET-1 level. Systemic levels of ET-1 are raised in a variety of pathological conditions associated with vasospasm including pregnancy-induced hypertension, cardiogenic shock and myocardial infarction[1-3].

It has been known for some time that the presence of liver metastases is associated with subtle alterations in hepatic blood flow[25]. The hepatic perfusion index (HPI), which is the ratio of hepatic arterial flow to total liver blood flow, is raised in such patients, even at a micrometastatic stage[26]. This phenomenon is caused by splanchnic vasoconstriction and a subsequent reduction in portal inflow. Animal studies suggest this is due to the presence of a circulating vasoconstrictor which is not one of the commonly identified physiological vasoactive agents[27]. Clinical studies looking at patients with liver metastases suggest that the HPI may be used as an accurate predictor of the presence of hepatic metastases[28]. Given that ET-1 is a potent vasoconstrictor with marked effects on the splanchnic bed and is produced by colorectal cancers, it might have a role in this phenomenon. However, in this study there was no significant difference in the plasma levels of ET-1 between patients with and without liver metastases.

In conclusion, this study demonstrated that in colorectal liver metastases endothelial cells contain raised levels of ET-1, and ET-1 expression is upregulated in both tumour cells and associated myofibroblasts. An increased level of ET-1 is also found in the plasma of patients with colorectal cancer with and without liver metastases. Whether or not ET-1 regulates tumour growth locally and systemically and whether its increased levels indicate progression of disease remains to be determined by future studies.

Short note

Carotid endarterectomy is safe in selected elderly patients

M. PEMBERTON, A. REID,
N. J. M. LONDON, P. R. F. BELL and
A. R. NAYLOR
Department of Vascular Surgery, Clinical Sciences Building, Leicester Royal Infirmary, Leicester LE2 7LX, UK
Correspondence to: Mr A. R. Naylor

The incidence of thromboembolic stroke increases with age, but 90 per cent of family doctors remain less likely to refer patients aged 70 years or more for carotid endarterectomy (CEA)[1] because it is perceived that they have a higher operative risk. This study is a prospective audit of the risk of death and/or stroke in elderly patients following CEA.

Patients and methods

A prospective, consecutive audit of 235 CEAs in patients aged 70 years or more (median 75 (range 70–88) years) was performed between January 1992 and July 1997. All patients had an ipsilateral stenosis of 70 per cent or greater; one-third had a contralateral occlusion or severe stenosis. During the same interval, 317 CEAs were performed in patients aged less than 70 years. Endarterectomy was performed under normotensive, normocarbic general anaesthesia with systemic heparinization, and routine shunting and patching. Transcranial Doppler (TCD) monitoring and completion angioscopy were introduced in 1992[2] and supplemented by routine postoperative TCD monitoring in October 1995[3].

Results

The death/disabling stroke rate in patients aged 70 years or more was 2·6 per cent (*Table 1*). Whilst the rate of death/any stroke was 3·8 per cent. The commonest single cause of morbidity was postoperative carotid thrombosis (five of nine patients). However, following implementation of a full perioperative monitoring programme in 97 elderly patients have now undergone carotid surgery without incurring an operative stroke (*Table 1*).

Table 1 Perioperative death and stroke rates following carotid endarterectomy

Age (years)	No. of CEAs	Death/disabling stroke	Death/any stroke
Overall			
40–69	317	8 (2·5)	14 (4·4)
70–90	235	6 (2·6)	9 (3·8)
Since introduction of full perioperative monitoring			
40–69	121	1 (0·8)	3 (2·5)
70–90	97	0 (0)	0 (0)

Values in parentheses are percentages. CEA, carotid endarterectomy

Paper accepted 16 August 1997

Discussion

This study suggests that CEA can be performed safely in selected elderly patients and that age alone should not be an automatic bar to consideration for surgery. The authors cannot, however, comment on selection of individual elderly patients as many may not have been referred to them. During the study, the main exclusion criteria for operation were a concurrent illness giving an anticipated survival of less than 2 years, dementia or an inability to maintain independent living. The final decision with regard to medical fitness for operation was made by a consultant anaesthetist.

It has been suggested previously that patients at highest risk of perioperative stroke are more susceptible to the effects of microembolization or impaired perfusion so that the margin for technical error is reduced[4]. Over the past 5 years the authors have implemented a policy of perioperative monitoring and quality control with the specific aim of identifying and correcting inadvertent technical error before it can cause harm. The fact that no elderly patient has suffered an operative stroke following full implementation of this policy suggests that such an approach may be an alternative to excluding elderly or other high-risk patients from surgery.

Although it is unarguable that long-term survival is reduced in the elderly patient, age alone should not be a reason to deny surgery which could prevent death or disabling stroke.

Trials and tribulations of vascular surgical benchmarking

D. C. BERRIDGE, D. J. A. SCOTT, J. D. BEARD* and L. HANDS†

Background Benchmarking is a new tool to assess the efficiency of different hospitals. Classification of operations using healthcare resource groups (HRGs) is related to parameters including number of cases, length of stay (LOS) and age profile.

Methods A National Comparative Database was used to compare three hospitals. Analysis was confined to the major HRGs involved with vascular/venous surgery.

Results For high-volume low-complexity varicose vein surgery, all three hospitals had similar numbers of patients and LOS. In contrast, the LOS for routine vascular operations in hospital A was double that in hospital B (16·3 *versus* 7·4 days). Hospital A had three times as many patients classified as 'other – peripheral vascular disease' as hospital C and six times as many as hospital B (329, 49 and 111 for hospitals A, B and C respectively). LOS following major amputation in hospitals A and C was nearly double that in hospital B (32·4, 18·3 and 33·6 days for hospitals A, B and C respectively).

Conclusion There were a number of significant variations between the three hospitals during the 9-month interval. Explanations included the methods of coding, local facilities including availability of rehabilitation beds and difference in the patients' age profiles. Benchmarking in its present format reveals a number of variations which may not necessarily reflect real differences in clinical performance.

Attempts to classify procedures with a view to comparison of the efficiency of different hospitals began in the USA in the late 1970s with the advent of diagnosis related groups (DRGs)[1]. These were, however, thought to be too detailed[2] for routine use in the UK, and hence were adapted to create a simpler version, healthcare resource groups (HRGs). HRGs are used to identify 'groups of patients expected to consume similar amounts of health care resources'.

Following modification, version 2 has been in use since 1992[3]. HRGs are now being used to 'benchmark', i.e. to compare clinical efficiency between different hospitals nationally[4]. Version 3 is nearing completion with a variety of modifications, allowing a more accurate allocation to clinical vascular practice. Every acute hospital will cost all surgical specialties using HRGs for the 1997–1998 contract year for both elective and emergency surgery.

One of the criticisms is that DRGs and HRGs were used initially to define complexity, but that they are increasingly based on length of stay (LOS), which forms the largest part of the cost of a hospital admission.

HRGs can be assigned automatically using the 'Healthcare Resource Grouper' (National Case Mix Office, Winchester, UK). This software programme uses a number of different criteria based on rank to allocate a particular HRG. The main criterion is whether any significant procedure has taken place. Primary and secondary diagnoses together with complications or comorbidity are included, but only if no procedure is recorded. Other factors included age in association with the primary diagnosis, and admission specialty.

In view of the increasing importance of HRGs, especially in contracting arrangements, currently collated data have been used to compare and contrast the performance of three major vascular centres.

Materials and methods

Data collected for use in a National Comparative Database (CHKS, 1996) was used with permission of CHKS and a nominated representative of each vascular unit (authors). Data analysis has been confined to the major HRGs concerned with vascular/venous surgery (*Table 1*). Methods and/or difficulties of coding were also noted.

Individual hospitals have not been identified and some comments will be left as observations rather than specific points, to help preserve anonymity.

The data were not modified or verified beyond that supplied from the comparative database. A 9-month interval from April to December 1995 was studied.

Results

There were no differences between hospitals in high-volume, low-complexity varicose vein surgery (e44); patients in this group are predominantly treated as day cases. Varicose vein surgery is largely unaffected by any differences in local facilities and social circumstances. Furthermore, it is protected from coding errors as a single code is used to cover all varicose vein operations (*Table 1*).

In contrast, there was a marked discrepancy in LOS between hospital A, and hospitals B and C in relation to e41 (emergency or complex vascular surgery) and e42 (routine vascular surgery). Furthermore, while hospital B had a comparatively short LOS following major

e41, Complex/emergency vascular operations; e42, routine vascular operations; e44, varicose veins; e45, interventional radiology; e46, diagnostic radiology; e48, major amputations; e50, 'other – peripheral vascular disease'. LOS, length of stay

amputations (e48), considerably more amputations were performed there than in either hospital A or C, which apparently took almost twice as long to discharge the same type of patient.

For other groups, coding difficulties or indeed errors appeared to be more frequent. Hospital A had nearly seven times as many patients grouped into e50 than hospital B and nearly three times as many as hospital C. At least part of this major difference was accounted for by the variation in coding between e45 and e46. Hospital A had only half the activity in these two HRGs compared with either hospital B or C. A large number (approximately 200) of the patients in e50 were assigned incorrectly and should have been categorized in e45 or e46. This is because of the lack of a direct 'feed' from the computer systems in the radiology department with those operating the HRG software. This work is now carried out manually to correct the problem.

Discussion

For varicose vein surgery, there is only one HRG code, so coding errors are rare; most patients are treated as a day case and rehabilitation deficiencies or social difficulties are not usually applicable.

By contrast the discrepancies between the three institutions in the e50 HRG reflect the major coding differences between the hospitals; the majority of these patients really belong to a different HRG. Differing coding procedures for emergency and elective cases also exist; some are based on the time of operation and others rely on the nature of admission (i.e. elective or emergency), retaining that classification even if the subsequent procedure is performed on an elective operating list during the same admission.

There are many factors which influence the stay in hospital for a certain procedure. Clinical practice can only suggest when admission and discharge are appropriate for a particular patient. The provision of physiotherapy, occupational therapy and social workers can have a major influence on the ability to perform care assessments and home visits before discharge as required under the Community Care Act. The ability to discharge otherwise fit patients to local convalescent or general practitioner-managed community beds is also variable. Some 'acute' surgical beds are undoubtedly used for convalescence in the absence of other available facilities.

HRGs will shortly be used as part of the contracting process. It is important therefore that the information used in these comparative analyses is accurate. Any major differences need to be studied to ensure that inappropriate coding, or insufficient local resources outside the control of the clinician, do not allow an unfavourable and inappropriate conclusion towards a particular HRG.

Reimbursement based on HRGs alone is susceptible to inadequate resourcing for patients who have the same operation but for different indications. Gupta and Veith[5] found that reimbursement almost matched costs when a femoropopliteal graft was done for claudication, but was often insufficient when the same operation was done for limb salvage.

Munoz *et al.*[6] examined 1169 patients having peripheral vascular surgery to determine if the cost per DRG could be predicted. Four clinical parameters were used: (1) emergency admission, (2) surgical intensive care unit admission, (3) infusion of plasma product or (4) blood transfusion. Patients with these parameters had significantly higher costs than patients in the same DRG without these factors.

Similarly, the source of referral is important. Patients referred by a physician were shown to incur a 146·5 per cent higher costing than those admitted directly to a surgeon[7]. Important contributory factors included more severe illness, increased diagnostic costs and delays in diagnosis or treatment.

Rhodes *et al.*[8] found that the duration of hospital stay for above-knee popliteal, below-knee popliteal, and tibioperoneal artery reconstructions was significantly different ($P < 0{\cdot}005$). More distal vascular procedures were also associated with higher morbidity and mortality rates. There were major differences between the patients treated by different surgeons with respect to age, previous ipsilateral surgery, crural bypass and co-morbidity. 'The most highly qualified surgeons dealt with the sickest patients.'

In the future, version 3 HRGs may remedy at least some of the coding difficulties highlighted in version 2. In addition, healthcare benefit groups are also being developed which will be used to stratify patients by severity of illness and co-morbidity.

It is essential that clinicians are actively involved in the verification of HRG coding to ensure that their workload and efficiency are accurately represented. Astute clinicians may evaluate any restrictions to rapid admission and discharge which will unfavourably influence their patients' hospital stay.

Acknowledgements

The authors acknowledge the help given so enthusiastically by Mrs Linda Sharpe, Clinical Audit, St James's University Hospital, Leeds, and are indebted to CHSK (Healthcare

Information Management, Alcester, UK) for permission for these data to be presented and published within the confidentiality agreement, and with the cooperation and permission of all three institutions.

Cryopreserved aortic homografts for patients who need simultaneous aortic and gastrointestinal surgery

P. R. VOGT, D. CANDINAS*, M. GENONI, G. ZÜND, R. SCHLUMPF* and M. I. TURINA

*Clinics for Cardiovascular Surgery and *Visceral Surgery, University Hospital, Rämistrasse 100, CH-8091 Zurich, Switzerland*
Correspondence to: Dr P. R. Vogt

Patients with intra-abdominal infection and a simultaneous vascular emergency are usually treated by extra-anatomic bypass grafting or *in situ* reconstruction with a prosthetic graft. Subsequent reinfection is common, leading to substantial mortality and morbidity rates[1]. Cryopreserved aortic homografts, being resistant to infection[2], allow safe *in situ* vascular repair and simultaneous surgery for the intra-abdominal infection.

Surgical technique

Between 1994 and 1996, six patients of mean(s.d.) age 60(12) years had surgery for simultaneous aortic and gastrointestinal problems. One patient had an aortobi-iliac bifurcation graft with resection of the left colon for intestinal ischaemia 2 years previously. He presented with recurrent rectal bleeding due to a fistula between the rectal stump and the prosthetic graft (*Fig. 1*). The prosthesis was replaced by an aortic homograft and the upper rectal stump closed. The second patient had an aortointestinal fistula involving an aortic bifurcation prosthesis penetrating the small intestine. A homograft was implanted and three segments of small intestine were resected. The third patient had perforated sigmoid diverticulitis covering an aortic aneurysm. The sigmoid colon was resected and a colostomy performed. The aneurysm was replaced by a homograft. The fourth patient had a ruptured infrarenal aortic aneurysm and ischaemic necrosis of the ascending colon. The right colon was resected leaving an ileostomy and transverse colostomy, and the aneurysm was replaced by a homograft. The final two patients developed aortoenteric fistulas originating from an anastomotic aneurysm of the prosthetic graft. Both were replaced by homografts. All vascular anastomoses were performed end to end using polypropylene sutures.

One patient died on the seventh postoperative day from a sudden cardiac event. Otherwise there was no perioperative morbidity including sepsis, organ failure or vascular problems. Mean(s.d.) hospital stay was 28(11) (range 14–35) days. Intravenous antibiotics were continued for 6 weeks. At mean(s.d.) follow-up of 16(6) (range 9–25) months all patients underwent computed tomography or magnetic resonance imaging without any evidence of reinfection, suture line complications or homograft stenosis.

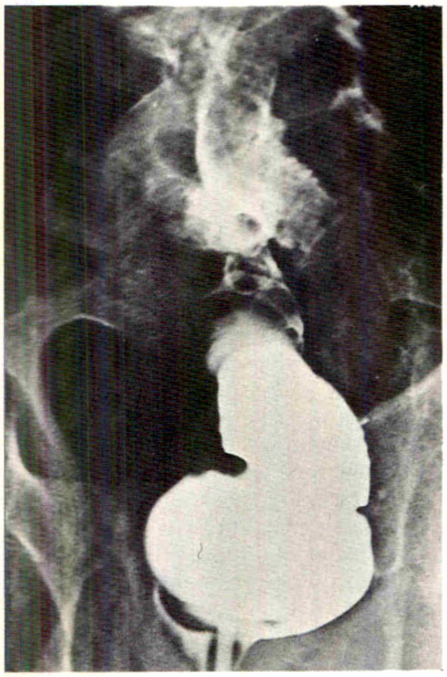

Fig. 1 Aortoenteric fistula from the upper rectal stump to an infrarenal bifurcation prosthesis leading to recurrent rectal bleeding

Discussion

Favourable results with cryopreserved homograft heart valves in the treatment of aortic valve endocarditis stimulated the use of cryopreserved aortic homografts for *in situ* repair of major vascular infections[2,3]. Standard extra-anatomic bypass or prosthetic *in situ* techniques in this situation are known to have high rates of reinfection, suture line dehiscence and requirement for long-term antibiotic treatment[1]. The use of homograft allowed a one-stage *in situ* repair in conjunction with limited antibiotic treatment for 6 weeks, a policy adopted from heart valve homograft surgery.

Although the long-term fate of cryopreserved aortic homografts is unknown[2], early deaths and morbidity[1] are the major concerns in the surgical treatment of aortic graft infections. The relatively short hospital stay and the absence of reinfection or anastomotic aneurysms in this series suggest that one-stage *in situ* homograft repair can be used safely when simultaneous aortic and gastrointestinal surgery is necessary.

Ruptured hepatocellular carcinoma as a complication of transarterial oily chemoembolization

C.-L. LIU, H. NGAN*, C. M. LO and S. T. FAN

*Departments of Surgery and *Diagnostic Radiology, The University of Hong Kong, Queen Mary Hospital, Hong Kong*
Correspondence to: Dr C.-L. Liu, Department of Surgery, The University of Hong Kong, Queen Mary Hospital, 102 Pokfulam Road, Hong Kong

Background Transarterial oily chemoembolization (TOCE) is frequently employed as a non-operative treatment for hepatocellular carcinoma (HCC). Serious complications of TOCE are well known but ruptured HCC as a fatal complication of TOCE has not been reported previously.

Methods A retrospective study was performed on all patients who received TOCE for treatment of HCC from January 1989 to October 1996; the complication of ruptured HCC within 2 weeks from the procedure was recorded.

Results During the study period, 391 patients received a total of 1443 sessions of TOCE (mean 3·7 sessions per patient) for the treatment of HCC, with an overall median survival of 10·4 months. Six patients developed ruptured tumour within 2 weeks after TOCE, resulting in an overall incidence of 1·5 per cent per patient or 0·4 per cent per procedure. All except one patient died 1–25 days after tumour rupture. Factors common to these six patients included: (1) male sex; (2) large tumour size (range 8–17 cm in diameter); (3) tumour located in the right lobe of the liver; (4) tumour ruptured after the first session of TOCE; and (5) TOCE performed as primary treatment without previous hepatic resection.

Conclusion Ruptured HCC is a serious complication of TOCE although the incidence is low. It occurred predominantly in men after the first session of TOCE for a large irresectable tumour of the right lobe.

Hepatocellular carcinoma (HCC) is one of the commonest cancers encountered in Asian countries and the incidence is increasing in the Western world. In China, HCC claims about 100 000 lives annually[1]. As only about 20 per cent of the tumours are considered resectable on presentation and a high incidence of postresectional recurrence has been observed[2–4], non-resectional therapies are frequently employed, the commonest of which is transarterial oily chemoembolization (TOCE). Although satisfactory survival results have been reported, complications of TOCE with significant morbidity are well known and adversely affect the outcome of patients[5]. Rupture is a catastrophic complication of HCC and has a high mortality rate. In the majority of cases, rupture of HCC occurs spontaneously although a history of minor trauma may be associated occasionally[6,7]. As far as the authors are aware, rupture of HCC as a fatal complication of TOCE has not been reported in the English literature.

Patients and methods

A retrospective study was performed on all patients who received TOCE as a primary treatment for irresectable HCC or as treatment for residual and recurrent disease after surgical resection from January 1989 to October 1996 in the Department of Surgery at Queen Mary Hospital, Hong Kong. Twenty-six patients who received systemic chemotherapy and TOCE after curative resection of HCC as part of a randomized trial of postoperative adjuvant chemotherapy during the study period were excluded from the study. TOCE was performed in the Department of Diagnostic Radiology, Queen Mary Hospital, Hong Kong.

Some 10 ml of Lipiodol (Lipiodol Ultrafluide; Laboratoire Guerbet, Aulnay-sous-Bois, France) was mixed with 10 mg of cisplatin by the pumping method into a milky emulsion of 20 ml. A torque-controlled 5-Fr catheter was inserted via a femoral artery and placed into a branch of the hepatic artery supplying the HCC or into the proper hepatic artery distal to the gastroduodenal artery if both lobes of liver were involved by tumour. Between 4 and 40 ml of the emulsion were infused into the liver depending on the size of the HCC. Light embolization of the feeding artery was then performed with small gelfoam pellets, which were prepared by cutting a gelfoam block into small cubes of approximately 1 mm in size. Injection of gelfoam was stopped when blood flow in the artery supplying the tumour slowed down but before occlusion occurred.

All patients were kept in bed for 12 h after the procedure and were prescribed oral antibiotic prophylaxis for 3 days and H_2-receptor antagonists for 1 week. The procedure was repeated at regular intervals for between 1·5 and 3 months. The details of all patients who developed rupture of HCC within 2 weeks of the procedure were recorded. Rupture of the HCC was diagnosed when the patient complained of abdominal pain with associated haemodynamic changes, a drop in haemoglobin concentration of 2 g/dl or more, and when haemoperitoneum was demonstrated by abdominal paracentesis. The clinical parameters of patients who developed ruptured HCC were compared with those of other patients without the complication.

Results

During the study period 391 patients received a total of 1443 sessions of TOCE (mean 3·7 sessions per patient). Some 333 patients (85·2 per cent) received TOCE as primary treatment for irresectable disease, and 58 (14·8 per cent) had TOCE because of recurrence or residual disease after resection. There were 337 men and 54 women. Mean tumour diameter was 7·5 cm before treatment. Median survival was 10·4 months and 132

Paper accepted 22 September 1997

patients were still alive with a median follow-up of 14 months at the time of preparation of the manuscript.

During the study period, six patients developed ruptured HCC 1–14 (median 2) days after the first session of TOCE, resulting in an overall incidence of 1·5 per cent per patient or 0·4 per cent per procedure. The size of the tumours that ruptured ranged from 8 to 17 (median 13·5) cm in diameter. Significant haemodynamic changes were observed in all patients; mean transfusion requirement was 2·0 (range 0–5) units. Five of the six patients died 1–25 (median 13) days after tumour rupture. Bleeding was the direct cause of death in two patients who died soon after rupture of the tumour. The cause of death was liver failure in the other three patients, although they survived the initial haemodynamic insult. One patient who experienced a minor rupture of HCC after TOCE was still alive at 6 months of follow-up. He received two further courses of TOCE and had a satisfactory response to treatment. No interventional procedure such as transarterial embolization, ligation of hepatic artery or surgical haemostasis was performed for these patients.

The clinical features of the six patients who developed ruptured HCC after TOCE are shown in *Table 1*. When compared with patients who did not have ruptured tumour after TOCE, the complication occurred predominantly after the first course of treatment in men who received TOCE as the primary treatment for large irresectable tumours located in the right lobe of the liver, although the difference was not statistically significant, probably because of the small number of patients.

Discussion

Although HCC is more prevalent in Asia and sub-Saharan Africa[8], it is a common global disease. The prognosis without treatment is poor, with a median survival of only 1·6 months[9]. Non-resectional therapies including TOCE play an essential role in the treatment of a large number of patients with irresectable or recurrent HCC. TOCE is a combination of targeted chemotherapy and arterial embolization to produce chemotherapeutic and ischaemic effects on the hepatoma. Yamada *et al.*[10] and others[11–17] have reported that the 1–5-year survival rates of patients with irresectable HCC after TOCE ranged from 51 to 6 per cent. Contraindications to TOCE include main portal vein thrombosis or obstruction by tumour, marked arteriovenous shunting to the portal or hepatic vein, and poor liver function. For the safety of TOCE therapy, it is important for clinicians who prescribe and for patients who undergo the procedure to understand the major complications involved and their predisposing factors. Complications of TOCE resulting in significant morbidity are well known and a treatment-related mortality rate of 4·1 per cent has been reported[5]. Fever, abdominal pain, ileus, nausea and vomiting after TOCE are commonly seen but usually subside within days. Chemotherapeutic and embolizing agents may cause chemical cholecystitis, pancreatitis, gastric and duodenal erosion, ulceration or necrosis if they are injected into these organs inadvertently. Infection of the necrotic tumour resulting in liver abscess and even serious sepsis have been reported[18,19]. Liver failure is a serious complication of TOCE and may result in death in patients with underlying advanced cirrhosis. Bile duct injury resulting in secondary sclerosing cholangitis[20], bile duct necrosis and biloma[21] have also been reported.

Table 1 Clinical features of patients who developed ruptured hepatocellular carcinoma after transarterial oily chemoembolization (group 1) and those without the complication (group 2)

	Group 1	Group 2
No. of patients	6	385
Sex ratio (M:F)	6:0	331:54
Age (years)*	55·7(5·1)	55·5(0·7)

Primary treatment for irresectable disease	6	327
Location of main tumour at right lobe of liver	6	262
Sessions of treatment*	1·3(0·3)	3·7(0·2)
Median survival (months)	0·4	10·5

*Values are mean (s.e.m.)

Rupture is probably the most catastrophic complication of HCC. There is a distinct geographical difference in the reported incidence of this complication, ranging from over 10 per cent in Asian countries[22,23] to less than 3 per cent in the UK[24,25]. Rupture of HCC as a complication of TOCE has not, to the authors' knowledge, been reported in the English literature. As observed in the six patients who developed the complication in the present series, the prognosis is extremely poor: only one patient survived for more than 1 month. When compared with patients who did not develop the complication and who had a median survival of more than 10 months, the complication of rupture of HCC after TOCE adversely affected the survival.

The mechanism of rupture of HCC after TOCE is unclear. It can be postulated to be related to tumour necrosis and increased pressure inside the friable tumour after TOCE. These changes are expected to be maximal in a large tumour undergoing the first session of treatment. The tumour may then rupture or split the overlying non-tumorous liver[26] with or without trivial trauma including diaphragmatic movement on the right lobe of the liver[27]. In addition, large tumours are considered to be at increased risk of rupture as they are more likely to contact the liver surface and to have an increased extent of extrahepatic protrusion[28]. The mechanism of rupture may also be related to vascular injury secondary to chemoembolization. Development of acute necrotizing angiitis with resultant infiltration of inflammatory cells and thickening of the arterial wall has been reported in arteries embolized with gelatin sponge particles[29,30]; the arterial wall becomes fragile because of inflammatory and reparative changes. Aso *et al.*[31] reported on five patients who developed multiple intrahepatic aneurysms after transcatheter arterial embolization. It can be speculated, therefore, that vascular damage occurring in the pathological vessels of the hepatoma after TOCE may result in bleeding into the tumour, which subsequently ruptures. However, further reports and studies are required to delineate the predisposing factors and mechanism of rupture of HCC after TOCE.

Management of patients with rupture of HCC following TOCE is difficult as they have already been diagnosed as having inoperable large tumours and impaired liver function. Two patients deteriorated rapidly and died soon after development of the complication before any intervention could be performed. Three other patients developed liver failure and died within 1 month, although they survived the initial haemodynamic insult without any interventional procedure.

In summary, ruptured hepatoma is a serious complication of TOCE, although the incidence is low. It occurs predominantly in men after the first session of TOCE for large irresectable HCC of the right lobe.

Improved survival in patients with rectal cancer: a population-based register study

M. DAHLBERG, L. PÅHLMAN, R. BERGSTRÖM* and B. GLIMELIUS†

*Departments of †Oncology and Surgery, Akademiska sjukhuset and *Department of Statistics, University of Uppsala, Uppsala, Sweden*
Correspondence to: Dr M. Dahlberg, Department of Surgery, Akademiska sjukhuset, S-751 85 Uppsala, Sweden

Background Between 1985 and 1989, only one centre in Sweden combined preoperative radiotherapy with total mesorectal excision (TME) in the primary treatment of rectal cancer. The aim of this study was to investigate whether this change in primary treatment had an impact on the outcome.

Method The survival rate of 94 262 patients with colorectal cancer from the total Swedish population between 1960 and 1989 was analysed.

Results A continuous improvement in relative survival rate occurred during the first year of follow-up for both colonic and rectal cancer. Some improvement was also seen during follow-up years 2–5, but this was much more pronounced during the last period (1985–1989) for rectal cancer in the county of Uppsala. The improvement was particularly marked during follow-up years 3–5.

Conclusion There are strong indications from this study that altered primary treatment for rectal cancer results in improved long-term survival.

Colorectal cancer is the fourth commonest malignant disease worldwide, with an estimated 678 000 new cases diagnosed in 1985[1] and about 394 000 deaths annually[2]. About one-third of these deaths occur from rectal cancer. In Sweden it is the third commonest form of cancer. As in other common cancers, little improvement in cure rates has occurred during the past few decades. Surgery is still the main treatment for patients with primary rectal cancer, but few studies have focused on the question as to whether the surgical technique has influenced long-term survival. As few controlled trials have been performed, comparisons between surgical techniques are based mainly on historical controls. Total mesorectal excision (TME), popularized by MacFarlane *et al.*[3], and extended lymphadenectomy, as practised by many Japanese surgeons[4], have both been claimed to improve not only local recurrence rate, but also long-term survival.

Adjuvant treatments, such as radiotherapy in rectal cancer and chemotherapy in both rectal and colonic cancer, were long considered to have no beneficial effects[5]. More recently a number of controlled trials have indicated that not only local recurrence rate in rectal cancer but also survival in colorectal cancer may be influenced by one, or a combination, of these modalities[6–17]. The survival benefits are still small, however, and their clinical relevance, particularly in combination with optimal surgery, is still under debate[18,19].

In a previous investigation overall and relative survival rates between the years 1960 and 1981 were studied on the basis of the Swedish Cancer Registry[20]. A slight improvement in relative survival was seen. The improvement was most pronounced during the first months of follow-up. Reduced postoperative mortality was considered to be the most likely major explanation for the trend towards a more favourable prognosis.

The University Hospital in Uppsala introduced preoperative radiotherapy and TME as a combined routine in 1985. At that time this was not widely performed in the rest of Sweden. In light of this the authors raised the following hypotheses. First, the relative survival rate of patients with rectal and colonic cancer would improve continuously during the first year after diagnosis over a 5-year diagnostic period to the same extent in all counties. Death during the first year is mainly a result of postoperative mortality and primarily irresectable tumours or metastatic disease found at diagnosis. Neither of these factors could be influenced by TME or preoperative short-term radiotherapy. Second, the relative survival rate of patients with rectal cancer in years 2–5 of follow-up would, in the county of Uppsala, show a particularly large improvement in the 5-year period of 1985–1989. There is no reason to expect such an improvement elsewhere. Third, no differences would be observed for colonic cancer, as those patients were not treated differently in the county of Uppsala.

The aim of the present study was to determine whether this change in primary treatment for rectal cancer has had any impact on survival in accordance with the predefined hypotheses. As patient selection may substantially influence the results, any comparisons of cohorts have to be population-based. The authors took advantage of the completeness of the Swedish Cancer Registry and compared the relative survival rate in the county of Uppsala with that in the rest of Sweden.

Patients and methods

Swedish Cancer Registry

Since 1958 all newly diagnosed cases of malignant disease have been reported to the National Cancer Registry. Repeated analyses have shown that registration is almost complete, with a deficit of less than 2 per cent[21]. The registry does not contain data on tumour stage, surgical curability or other clinical factors. Dates and causes of death are transferred annually from the Causes of Death Registry by computerized link.

Patients

The study period covered 1960 to 1989. During that period, 1736 cases of invasive carcinoma of the colon and 1060 cases of invasive carcinoma of the rectum were reported to the registry from the county of Uppsala, and 69 657 and 39 855 cases, respectively, in the rest of Sweden (*Table 1*). *Table 1* also shows

carcinoma diagnosed at autopsy, patients lost to follow-up, and patients with a second, metachronous cancer, all of whom were excluded from the analyses. The number lost to follow-up was very small (less than 0·5 per cent) and was mainly a result of emigration or incorrect individual identification numbers, which made it impossible to match records from different registries. The patients included were divided into six groups according to predefined 5-year periods of diagnosis. The deadline for follow-up was 30 April 1994.

Surgical technique

In the mid-1980s TME was introduced at the University Hospital in Uppsala. Separate high ligations of the inferior mesenteric vessels were performed to define the proximal limits of the lymphatic clearance. The rectum was mobilized with sharp dissection under direct vision in the avascular plane outside the fascia rectalis and Denonvillier's fascia, excising the whole mesorectum leaving the somatic structures of the autonomic nerve plexuses behind. This is in contrast to 'standard surgery', applied earlier in Uppsala, in which the mesorectal envelope was, in most patients, entered by blunt dissection.

In upper-third tumours there was no strict application of the total removal of the whole length of the mesorectum. In these patients the mesorectum was divided horizontally at least 5 cm below the tumour.

Statistical methods

Observed survival rates (OSRs) for all causes of death were calculated by the actuarial method[22]. To correct these rates of death to exclude causes other than colorectal cancer, relative survival rates (RSRs) were calculated as the ratio of the OSR to the survival rate expected during the same period in a group of people in the general population, divided according to 5-year age groups and sex[23,24]. The standard error (s.e.) of the OSRs was calculated from Greenwood's formula[25], and the s.e. of the RSRs was computed as s.e. (OSRs)/expected survival[26]. A 95 per cent confidence interval (c.i.) was calculated from point estimates and s.e. on the basis of a normality assumption.

Multivariate analyses were performed to estimate the independent effects of age, diagnostic period, sex, county (Uppsala county *versus* others), and year of follow-up. The primary aim of these analyses was to test the predefined hypotheses regarding survival in the county of Uppsala compared with all other counties. The analyses were based on grouped annual data and a generalization of the proportional hazards model in which the rectal cancer hazard rate was assumed to be additive to the hazard rate in the general population[27]. This model was formulated as a generalized linear model and estimates were obtained by the maximum likelihood method, using GLIM (Numerical Algorithms, Oxford, UK) statistical software[28]. Categorical explanatory variables were used. Stratified models and models with interaction terms were also estimated. (The authors model the excess hazard among patients with rectal cancer compared with the general population, i.e. 'the disease-specific survival with respect to rectal cancer'.) Data from the first 5 years of follow-up were used.

The estimated models were compared with respect to deviation, which describes the fit of the model. Deviation of the same order as the degrees of freedom is normally taken as an indication of a reasonable fit. The authors used the difference in deviation in combination with the pattern and size of the parameter estimates as an indicator of the quality of the different models. The results are given as relative hazard (RH) of dying from rectal cancer with 95 per cent c.i.

Results

Five-year RSRs showed that patients with cancer of the colon had a somewhat better prognosis than those with rectal cancer in all 5-year time periods except in the county of Uppsala during the period 1985–1989, when the opposite was seen (*Table 2*). Women had a generally more favourable prognosis than men (data not presented). More than 90 per cent of mortality from colorectal cancer occurred within the first 5 years (*Table 2*; these results are similar to those presented previously for the period 1960–1981[20]). The 1-, 5-, and 10-year RSRs for both rectal and colonic cancer were higher the later that the cancer was diagnosed (*Table 2*), and the improvement was most pronounced during the first year of follow-up. However, there was a particular reduction in the risk of death among patients with rectal cancer diagnosed in the county of Uppsala in 1985–1989 between 1 and 5 years after diagnosis (*Table 3*).

Survival curves comparing patients diagnosed before and after 1985 also showed an improved survival rate for patients with rectal cancer diagnosed after 1985 in the county of Uppsala that is not seen in the rest of Sweden (*Fig. 1*). No such difference was seen for cancer of the colon (data not presented). For 1985–1989, the 5-year RSRs for cancer of the rectum were 61·9 per cent (95 per cent c.i. 53·2–70·6) in the county of Uppsala and 50·9 per cent (95 per cent c.i. 49·5–52·3) in the rest of Sweden.

Table 3 Absolute and relative risks of death during different time periods after diagnosis among patients with colonic and rectal cancer

	County of Uppsala				Rest of Sweden			
Year of diagnosis	Death risk (year 0–1)	Relative death risk (year 0–1)	Death risk (years 1–5)	Relative death risk (years 1–5)	Death risk (year 0–1)	Relative death risk (year 0–1)	Death risk (years 1–5)	Relative death risk (years 1–5)
Colonic cancer								
1960–1964	35·1	1·00	23·7	1·00	36·7	1·00	34·4	1·00
1965–1969	31·4	0·89	36·9	1·56	33·3	0·91	32·2	0·93
1970–1974	22·9	0·65	17·3	0·73	32·7	0·89	31·6	0·91
1975–1979	27·2	0·77	26·2	1·11	30·6	0·83	30·3	0·88
1980–1984	26·3	0·75	18·9	0·80	26·7	0·72	27·6	0·80
1985–1989	22·0	0·63	35·5	1·50	24·7	0·67	27·5	0·80
Rectal cancer								
1960–1964	33·3	1·00	42·0	1·00	33·7	1·00	44·9	1·00
1965–1969	28·2	0·85	46·6	1·11	30·3	0·90	40·4	0·90
1970–1974	23·2	0·70	41·0	0·98	27·9	0·83	40·2	0·90
1975–1979	24·9	0·75	29·7	0·71	24·9	0·74	41·2	0·92
1980–1984	25·1	0·75	41·2	0·98	23·6	0·70	36·6	0·82
1985–1989	21·6	0·65	21·1	0·50	21·4	0·64	35·2	0·78

Values are percentages with the period 1960–1964 taken as base. Death risk years 1–5 are calculated as 100× (1 − relative survival rate (RSR) (after 5 years)/RSR (after 1 year)). Note that 'year 0–1' is the first year of follow-up, 'year 1–5' is the second, third, fourth and fifth year of follow-up (follow-up years 2–5), as 'year' refers to a point in time and 'follow-up year' is a time interval

Corresponding figures for the period of 1960–1984 were 43·8 per cent (95 per cent c.i. 39·2–48·4) and 42·8 per cent (95 per cent c.i. 42·1–43·5) respectively.

Tables 4 and *5* show the results of the multivariate modelling for rectal cancer. The authors started by assuming that the RH in the county of Uppsala (compared with the rest of the country) was unchanged over the entire period of 1960–1989. RH was 0·92 after adjustment for effects of the other variables, a reduction that was not significant (*Table 4*). Exclusion of the latest period brought RH even closer to one (RH, 0·95). An analysis based on the period of 1985–1989 showed a considerably reduced hazard for the county of Uppsala (RH, 0·79), but this was not statistically significant. A corresponding analysis restricted to follow-up years 2–5 further reduced RH to 0·61, which was significantly smaller than 1.

To study the effects further in the county of Uppsala compared with the rest of the country, the authors postulated models that included interaction effects between county and follow-up year. This allowed RH in the county of Uppsala to vary during different follow-up years (compared with the rest of Sweden). In the period 1960–1984 no tendency towards different effects was seen in this county in different follow-up years, as shown by RHs that varied rather randomly around 1 (*Table 5*). In the latest period, 1985–1989, there was no difference in RH during the first year of follow-up (RH, 1·01) between Uppsala and other counties. During the second year there was some reduction in the county of Uppsala (RH, 0·86) and during follow-up years 3–5 there was a considerable reduction (RH, 0·31, 0·52 and 0·60). Because of the small number of deaths in this county, this reduction did not reach statistical significance.

Discussion

This study provides evidence that the change in primary treatment for rectal cancer has improved the long-term survival rate in one Swedish county. However, before drawing firm conclusions about the register-based data, some issues need to be discussed. First, not all patients in the county of Uppsala had both interventions, and some patients in other counties had either one or both of them. Second, a number of other diagnostic and therapeutic measures may also have influenced the relative survival figures. Third, different registration routines might have led to changes.

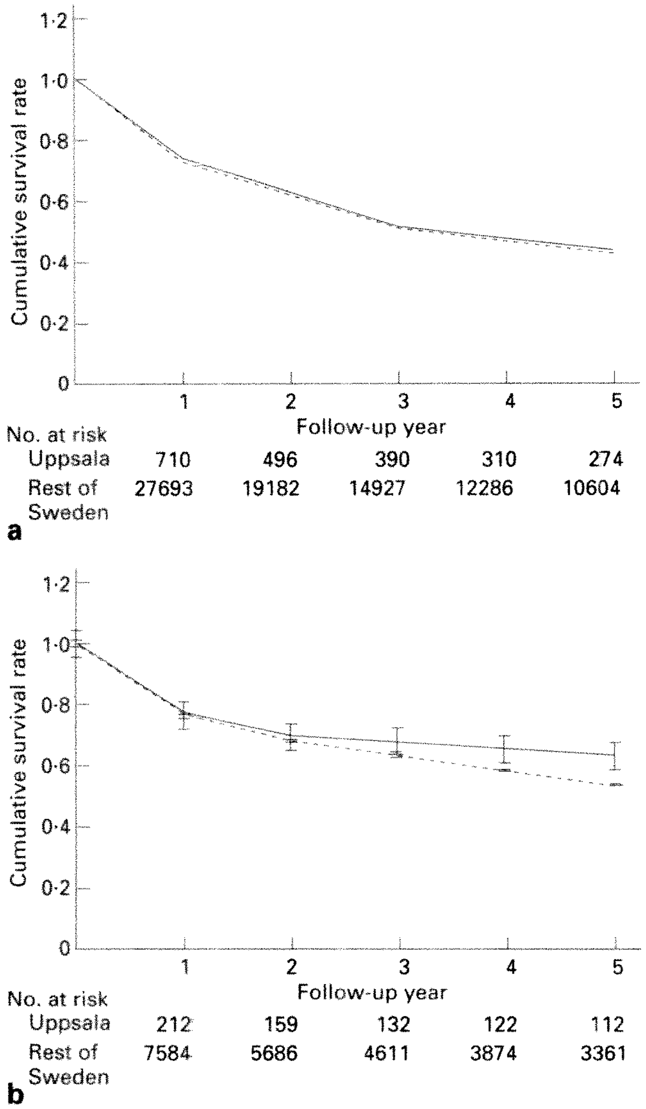

Fig. 1 Cumulative relative survival rate for patients with rectal cancer diagnosed between **a** 1960 and 1984, and **b** 1985 and 1989 for the county of Uppsala (——) and the rest of Sweden (– – – –). Bars are 95 per cent confidence intervals

Table 4 Estimates of the relative hazard of dying from rectal cancer in the county of Uppsala compared with all other counties in multivariate models containing follow-up year, sex, period, county and age

Period	Relative hazard
1960–1989	0·92 (0·82–1·04)
1960–1984	0·95 (0·83–1·08)
1985–1989	0·79 (0·59–1·07)
1985–1989 (follow-up years 2–5)	0·61 (0·40–0·95)

Values in parentheses are 95 per cent confidence intervals

Table 5 Relative disease-specific hazard in the county of Uppsala compared with all other counties, based on interaction models

	1960–1984	1985–1989
Follow-up year	Relative hazard	Relative hazard
1	0·94 (0·78–1·12)	1·01 (0·69–1·48)

5	1·04 (0·54–1·99)	0·60 (0·12–2·87)

Values in parentheses are 95 per cent confidence intervals

Rectal cancer surgery has always been carried out at university, district general and local hospitals in Sweden, and only occasionally by surgeons subspecializing in colorectal surgery. However, in the mid-1980s a few Swedish surgeons learned the TME technique and started to practise it. It is estimated that about 50 per cent of patients in the county of Uppsala underwent TME between 1985 and 1989. The corresponding figure in other counties may have varied between 0 and 5 per cent.

Preoperative radiotherapy using 5 × 5 Gy was first used in Uppsala in 1978[30]. Two randomized trials were initiated in Sweden in 1980, one in the Uppsala region, and one in the Stockholm–Gotland region and the city of Malmö. The Uppsala trial ceased recruitment in December 1985[31], and it was then recommended that all patients should have preoperative radiotherapy. The Stockholm–Malmö trial continued to include patients until February 1987[15], when the nationwide Swedish Rectal Cancer Trial was initiated, in which practically all Swedish hospitals participated, randomizing between surgery alone and surgery with preoperative radiotherapy[32]. According to an audit of participating hospitals, about 55 per cent of the eligible patients were included in the study (unpublished data, M. Dahlberg, L. Påhlman, B. Glimelius). It can be estimated that during 1985 and 1989, 35–45 per cent of patients with rectal cancer in the county of Uppsala had preoperative radiotherapy, whereas this figure varied between 5 and 20 per cent in the other counties.

Adjuvant chemotherapy was not used in Sweden during 1985–1989 and the effects of chemotherapy for metastatic disease on survival are limited[33,34]. There is no evidence of difference in registration patterns or earlier diagnosis over this period. Taken together, the authors do not consider that these, or any other factor, could have influenced the main conclusion, namely that the introduction of TME with preoperative radiotherapy on a more general basis in the county of Uppsala improved survival rates in patients with rectal cancer beyond 1 year after diagnosis. As TME has never been tested in a randomized trial but preoperative radiotherapy has[10,12,14–17], it can thus be claimed that at least radiotherapy is of importance, but it is the authors' belief that the improvement relates to a combination of the two interventions.

One limitation of this study is that, in spite of the very large number of observations overall, the number of patients in the group of specific interest (Uppsala patients with rectal cancer from 1985 to 1989) is rather small.

However, the results remain significant but require verification when data on larger groups of patients are available.

The authors believe that the rate of survival is improved, but cannot give an estimate of the degree of improvement. All patients within the defined populations were included in the analyses, i.e. both those who underwent the interventions and those who did not. Relative survival is also influenced beyond 1 year after diagnosis in primarily advanced cases and very old patients who cannot be treated adequately. These facts together indicate that the observed difference (11 percentage points; 5-year RSR 62 *versus* 51 per cent) is a minimum figure. It is possible that some of the survival benefit found in the Swedish Rectal Cancer Trial[12] (48–58 per cent) could have been achieved with TME alone if practised on a more general basis. In light of the difficulties experienced in performing controlled clinical trials dealing with surgical techniques this is unlikely to be proven[35]. Indirect evidence such as that provided by the present study, although confounded by the positive effect of preoperative radiotherapy, thus has to be the basis for the selection of treatment strategies.

Short note

Local anal hypothermia with a frozen finger: a treatment for acute painful prolapsed piles

Y. EL ASHAAL, V. PREM CHANDRAN,
M. N. SIDDIQUI and A. J. W. SIM

The management of patients with acute painful prolapsed piles remains controversial. Anal dilatation and haemorrhoidectomy have a place, but the topical application of crushed ice is 'time dishonoured'[1]. This paper describes a method to produce local anal hypothermia and effect rapid symptom relief.

Materials and methods

Local anal hypothermia is achieved with a frozen finger made from a standard surgical glove; all fingers except the index finger are knotted at the base, the glove is turned inside out, filled with water, tied at the wrist and frozen. This produces a piece of ice covered by a single finger and most of the hand of the glove. After diagnosis the patient is positioned in the left lateral position and an attempt is made to reduce the piles; irrespective of the result of this the frozen finger is lubricated and inserted into the anal canal. The bulky part of the 'frozen finger' remains outside the canal and is taped in position.

Results

Fourteen patients with acute onset painful prolapsed piles have been treated with the frozen finger. When necessary pain was controlled initially with pethidine. Patient data are shown in *Table 1*. The frozen finger was inserted three to four times in each patient. Most found the initial insertion uncomfortable but within 3–4 min there was relief of pain which lasted up to 4 h. The finger remained frozen for 15–20 min. One patient required more than three doses of pethidine and ten received either no pethidine or one dose before insertion. Most pile masses decreased in size and remained reduced after two to three insertions.

Discussion

If cooling is to be effective in anal canal disease the cold must be applied inside and around the anal canal. The topography of the perianal region makes it difficult to maintain constant contact of cold inside and around the anal canal and it is unlikely that effective cooling occurs with external application alone. Successful treatment of haemorrhoids by insertion of a 'cold stick' ('The Nine Minute Wonder') was reported in the *Arab Times* of Sunday 7 November 1982. Healing of anal fissures after use of a special dilator (Anokryo; PakuMed, Essen, Germany) cooled to − 15°C has been reported (M. K. Koudani and F. Beersick, personal communication). The technique described here uses a frozen finger, a device which is cheap and easy to make.

In painful prolapsed piles the anal canal is painful and 'tight' because the internal sphincter is contracted, there is voluntary contraction of the external sphincter and there are swollen oedematous haemorrhoids. Cold probably produces analgesia by reducing cellular metabolism and decreasing sensory nerve transmission; similarly cold relaxes the sphincters by a reduction in motor nerve and muscle function, decreasing the constriction of the prolapsed piles. Cold also reduces tissue swelling and oedema by producing local vasoconstriction.

This report demonstrates that the frozen finger reduces the pain and swelling of painful prolapsed piles. The proper place of this treatment should be established by a controlled clinical trial against standard therapies.

Significance of local recurrence of rectal cancer as a local or disseminated disease

S. MAETANI, H. ONODERA, T. NISHIKAWA, H. MORIMOTO, K. IDA*, the late O. KITAMURA† and M. IMAMURA

Background The nature of 'local recurrence' of rectal cancer remains unclear.

Methods Fifty-nine patients with locally recurrent rectal cancer who underwent extended repeat resections including total pelvic exenteration (39) and sacrectomy (43) were reviewed. Twelve patients had distant metastases before or at the time of repeat resection.

Results The 5-year survival rate was 25 per cent. A second recurrence occurred in 45 patients including five of the eight 5-year survivors. Thirty-six of these recurrences had locoregional manifestations and 29 had distant metastases. Of 18 prognostic factors examined, the most significant determinant was the postoperative carcinoembryonic antigen doubling time (CEADT), followed by the preoperative CEADT, carcinoembryonic antigen (CEA) level and occurrence of distant metastases, in decreasing order. Late onset of first recurrence was also a favourable indicator. Thus, the growth rate of the tumour had a more profound impact on survival than the current extent of tumour progression. After operation the CEADT was reduced in patients with second recurrence ($P = 0{\cdot}05$).

Conclusion Locally recurrent rectal cancer is a manifestation of disseminated disease spreading locoregionally and often to distant organs with a low probability of long-term cure. However, survival varies widely depending on the tumour growth rate, which is biologically predetermined and is also influenced by surgery.

Recently, there has been a number of reports on the results of surgery for local recurrence of rectal cancer[1–10]. According to these studies, resection can provide good palliation and prolonged survival compared with other therapeutic modalities, with 5-year survival rates ranging from 9 to 40 per cent. However, these advantages are tempered by the high incidence of postoperative complications[3,6,9,10] and the early development of a second recurrence[3]. Such events further diminish the quality of life of the patients with double stomas, and may even shorten survival. The following questions remain unanswered: (1) whether recurrence represents localized or disseminated disease; (2) what proportion of patients are really cured by surgery; and (3) which patients benefit from surgery with prolonged survival. To answer these questions patients developing recurrence despite curative surgery must undergo a highly radical repeat resection, and they must be followed for more than 5 years using modern diagnostic procedures. Few studies seem to satisfy these criteria. The purpose of this report was to analyse data from 59 consecutive cases in an attempt to answer these questions and to gain a fresh insight into the nature of this disease.

Patients and methods

Fifty-nine consecutive patients underwent wide resection for 'local recurrence' of rectal cancer between November 1978 and December 1996. Age ranged from 39 to 77 (median 61) years; there were 32 men and 27 women. The initial resections performed for the primary rectal cancer were total pelvic exenteration in two patients, abdominoperineal excision in 36 and sphincter-saving resection in 21. Before the surgery for locoregional recurrence, five patients had undergone liver resection and two had pulmonary resection for distant metastases. At repeat resection, four had liver metastases, two had lung metastases and one had both. In two patients, the concurrent metastases occurred after resection of the first metastases.

The operative techniques employed for recurrence were similar to those described previously[3], with some modifications[11]. All operations were performed with curative intent, although at least four patients were later found to have non-curative disease. Total pelvic exenteration was performed in 39 and sacrectomy in 43 patients, 11 of whom underwent additional bony resections including inferior pelvectomy[3] in seven. Pelvic exenteration was combined with sacral resection in all but two patients. Hepatectomy was performed simultaneously in four of the patients with concurrent liver metastases. In addition to inevitable loss of the lower portion of the sciatic nerve plexus in conjunction with sacrectomy, nine patients had the remaining plexus partly removed. Another two had unilateral and one had bilateral resection of the obturator nerve. Adjuvant radiotherapy was performed in 26 patients. A further five patients received radiotherapy after the second recurrence. After operation, almost all patients received oral chemotherapy of either Tegafur (600–800 mg daily; Taiho, Tokyo, Japan) or a combination of uracil with Tegafur (400–600 mg).

The patients were regularly examined for signs of recurrence by means of serum carcinoembryonic antigen (CEA) measurements, ultrasonography of the liver, chest radiography and computed tomography as well as magnetic resonance imaging and bone scintigraphy as indicated. The survival data were analysed with regard to: (1) sex; (2) type of initial surgery; (3) location of the primary tumour; (4) lymph node status; (5) histological grade of differentiation; (6) disease-free interval; (7) interval from the initial surgery to repeat resection; (8) CEA level at repeat resection; (9) doubling time of CEA (CEADT) before repeat resection; (10) CEADT after repeat resection; (11)

Paper accepted 10 July 1997

distant metastases before or at repeat resection; (12) operating time for repeat resection; (13) blood loss; (14) involvement of adjacent pelvic viscera; (15) involvement of pelvic walls; (16) extent of pelvic visceral resection; (17) resection of pelvic walls; and (18) radiotherapy before the second recurrence.

The preoperative and postoperative CEADTs were obtained for 42 and 44 patients respectively in whom CEA level was serially determined. CEADT was calculated as log 2 ÷ regression coefficient, which in turn was obtained by plotting log CEA concentration against time. If log CEA did not show a linear increase in certain periods, as was often the case, regression analysis was performed for the relatively linear interval. In six patients before operation and in three after operation in whom CEA levels did not rise with time, CEADT was set to an arbitrary value of 6000 days, which was greater than any of the observed values.

To assess the prognostic value of each variable, the patients were divided into two groups by that variable and survival rate was compared between groups in terms of hazard ratio (log rank test) and difference in 5-year survival rate (z test). The Cox regression analysis was used to select the optimal set of independent predictors. Patients were divided into those with a short survival and those with a longer survival, depending on whether death from cancer occurred within 3 years (excluding cases censored within 3 years). The distribution of each variable was then compared between these groups using the χ^2 test and Wilcoxon rank test. Associations of one variable with others were evaluated by Spearman rank correlation. Logarithmic transformation was made for all positive continuous variables showing skewed distributions to the right.

Results

Survival and second recurrence

The overall 5- and 10-year survival rates were 25 and 15 per cent respectively (*Fig. 1*). Eight patients survived 5 years but five of these developed second recurrences and three died from the disease. The patient surviving for longest has been alive without disease for 152 months since pelvic exenteration and inferior pelvectomy (patient 13). Another patient (patient 26) has been disease free for 89 months since a third resection for a lung metastasis which occurred 13 months after resection of the recurrence.

Forty-five patients have developed second recurrences, of which 16 were locoregional recurrences, nine were distant metastases, and the remaining 20 had both

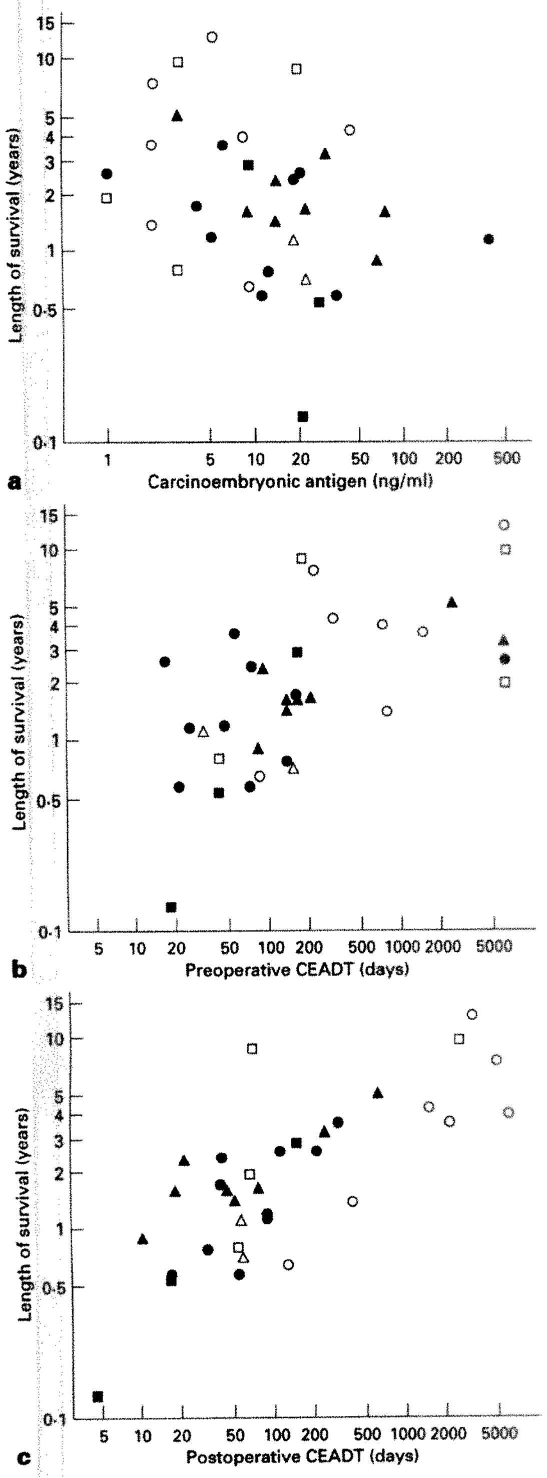

Fig. 2 Correlation of survival time with three prognostic factors. a Carcinoembryonic antigen (CEA) level ($r_s = 0{\cdot}43$ (95 per cent confidence interval (c.i.) 0·06–0·69); $t = 2{\cdot}44$, 26 d.f., $P = 0{\cdot}02$); b preoperative values of CEA doubling time (CEADT) ($r_s = 0{\cdot}53$ (95 per cent c.i. 0·19–0·75); $t = 3{\cdot}18$, 26 d.f., $P = 0{\cdot}004$); c postoperative values of CEADT ($r_s = 0{\cdot}83$ (95 per cent c.i. 0·67–0·92); $t = 7{\cdot}66$, 26 d.f., $P < 0{\cdot}001$). Data from the same 34 patients were used. ○, Living without disease; △, living with locoregional recurrence; □, living with distant recurrence; ▲, death from locoregional recurrence; ■, death from distant recurrence; ●, death from both locoregional and distant recurrence. Six patients censored within 2 years were excluded from calculations

components. The survival curve showed a rapid decline during the first 12 months. Of 13 deaths within 12 months, two were a result of postoperative complications. Of the remaining 11 deaths, two were because of locoregional recurrences alone, three a result of distant metastases, and the remaining six deaths were associated with both types of recurrence. In four patients with concurrent distant metastasis, the initial plan for staged surgery was abandoned as the disease rapidly progressed to multiple metastases. The authors consider that survival would not have been improved in these patients even if the first metastasis had been resected simultaneously.

Factors influencing outcome

If hazard ratio was used as a criterion to assess the prognostic value of each variable in survival analysis, postoperative CEADT was the most significant predictor of survival, followed by preoperative CEADT, CEA concentration and occurrence of distant metastases, in decreasing order (*Table 1*). This order remained unchanged when analyses were repeated using the same 34 patients for whom complete data on these four variables were available. A Cox stepwise analysis excluding postoperative CEADT (which was not obtainable at the time of repeat resection) showed that preoperative log CEADT was the only independent predictor ($\chi^2 = 8{\cdot}5$, 1 d.f., $P = 0{\cdot}004$).

Similar results were obtained when the distribution of each variable was compared between the shorter (less than 36 months) and longer (36 months or more) survival groups. As expected, postoperative CEADT was the strongest discriminator between the two groups despite an extremely wide range of distribution ($z = 4{\cdot}72$, $P < 0{\cdot}001$, Wilcoxon test), followed by preoperative CEADT ($z = 3{\cdot}44$, $P < 0{\cdot}001$). Compared with both CEADTs, absolute CEA level was less powerful in predicting patient survival ($z = 2{\cdot}4$, $P = 0{\cdot}02$). These three variables were again in the same prognostic order when assessed by their correlations with survival time (*Fig. 2*). As for distant metastases, ten of the 31 short-term survivors had distant metastases at or before resection, whereas only one of the 17 patients in the longer survival group had distant metastases ($\chi^2 = 4{\cdot}32$, 1 d.f., $P = 0{\cdot}04$).

In the shorter survival group, CEADT was significantly shortened after operation, indicating that tumour growth is accelerated after operation ($z = 2{\cdot}34$, $P = 0{\cdot}02$). This was also confirmed by applying the sign test to 18 pairs of data; CEADT was shortened in 14 cases after operation, compared with four patients in whom it was prolonged ($P = 0{\cdot}03$). Overall, excluding patients without second recurrence, CEADT was reduced in 19 patients whereas it was prolonged in eight ($P = 0{\cdot}05$), and the Spearman correlation between preoperative and postoperative CEADTs was 0·47 ($P = 0{\cdot}01$). There was no difference in postoperative CEADT between different types of second recurrence.

Although of lesser prognostic significance, both disease-free interval and time to repeat resection were also related to survival (*Table 1*). This is exemplified by two women who underwent repeat resection more than 100 months after the initial abdominoperineal excision. In one patient (patient 19) it took a further 96 months for the second recurrence to develop in the lung. The other woman (patient 37) has remained disease free for 49 months after combined resection of the right sciatic nerve plexus which was involved by the recurrence.

None of the other prognostic factors (not listed in *Table 1*), including the type of the initial surgery, extent of repeat resection, radiotherapy and invasion of the bladder, was significantly correlated with survival.

Discussion

Categorically, 'local recurrence' of rectal cancer has a broad aetiology. At one extreme is inadequate resection resulting in a localized residual tumour, which can be eradicated by simple repeat resection. According to Polk and Spratt[12], patients with improved survival were among those whose initial resections were performed at other hospitals and were less extensive than is usually considered adequate. Hoffman *et al.*[5] suggested that surgery after initial local excisional procedures must be placed into a separate category.

There were no such patients in this series. Despite highly radical surgery, second recurrences developed in 80 per cent of patients undergoing resection of recurrences, with a locoregional component more frequently observed than distant components. Furthermore, 21 per cent died from the disease within 1 year. Five of eight 5-year survivors developed a second recurrence. Consequently, the survival curve showed a progressive decline after 5 years, leaving only one 10-year survivor. In the series of Wanebo *et al.*[6], which included 47 patients undergoing curative sacrectomy, the 5- and 10-year survival rates were 33 and 11 per cent respectively. The survival curve indicated that one patient survived 10 years. To the authors' knowledge, there has been no other report of 10-year survival in patients undergoing such extended resection, although there are a few reports of long-term survivors after less extensive repeat resections[13]. Such long-term results appear to be worse than those after curative resection of distant metastasis to the liver or lungs.

It is generally recognized that one of the major determinants of prognosis is the extent of tumour progression, which is reflected by the size of the tumour[7,14], invasion of the pelvic wall[3,6] or adjacent viscera[14], lymph node involvement[6], distant metastases[3] and serum CEA level[6,7]. Association of poor survival with a positive surgical margin[6–9,14,15] may also be explained by tumour extension beyond the scope of resectability, although inadequate resection is another possibility. Development of metastases in remote organs has generally been regarded as the final stage of disease and the worst prognostic indicator. Of 12 patients who presented with distant metastases at or before the time of repeat resection, 11 died within 36 months. Nevertheless, the present study showed that a rapid rise of CEA concentration or decreased CEADT is closely associated with poor survival. Although postoperative CEADT was the most powerful determinant, preoperative CEADT also correlated with survival more closely than CEA level. These results could be interpreted as indicating that after curative surgery the growth rate of the tumour is a more important determinant of prognosis than the current extent of the tumour. On the other hand, the significant correlation between the preoperative and postoperative CEADTs shows that the growth rate is biologically predetermined. This interpretation is consistent with the observation[13,16,17] that the onset of recurrence is very late in some long-term survivors, although such a correlation has not been demonstrated in other reports[6,9,10].

In patients with a second recurrence, CEADT was significantly shortened after surgery, a finding consistent with occasional observations that after operation the residual tumour regains its previous size far more quickly than the preoperative growth of the same tumour. Thus, tumour growth may be accelerated by surgery, causing the early development of a second recurrence, and the extremely wide range of observed CEADT values should not be regarded merely as gross error. Initially, it was suspected that the magnitude of operative intervention was a factor influencing growth, but no significant decrease in postoperative CEADT was demonstrated after combined resection of the pelvic wall or viscera, or in groups with longer operating time or greater blood loss.

Based on these findings it is suggested that the major cause of local recurrence is cancer dissemination in surgical wounds and distant organs, rather than inadequate resection of the primary tumour, an aetiology favoured by many surgeons[18,19]. This mode of recurrence is more likely in Japan where extended surgery has been practised[20]. Although this concept is not new[21–25], there has recently been additional evidence to support it, such as port-site recurrence after laparoscopic surgery[26]. Cancer recurrence has also been described in one of the surgical incisions in the thigh where the gracilis was isolated for sphincteroplasty[27]. The clinical implications of this concept are important because, if it is valid, the incidence of recurrence could be reduced by specific prophylactic measures[28,29] including adjuvant radiotherapy and chemotherapy.

In conclusion, the majority of local recurrences of rectal cancer represent a local manifestation of a disseminated disease spreading locoregionally and often to distant organs with a low probability of long-term cure. However, survival time varies widely depending on the growth rate of the tumour, which is biologically predetermined, and also influenced by surgery. The mechanisms controlling the growth rate have yet to be elucidated.

Effect of the introduction of total mesorectal excision for the treatment of rectal cancer

E. CARLSEN, E. SCHLICHTING, I. GULDVOG, E. JOHNSON and R. J. HEALD*

*Surgical Department, Ullevaal Hospital, University of Oslo, Oslo, Norway and *Colorectal Research Unit, Basingstoke District Hospital, Basingstoke, UK*

Correspondence to: Dr E. Carlsen, Surgical Department, Ullevaal Hospital, University of Oslo, 0407 Oslo, Norway

Background Total mesorectal excision (TME) has been reported to reduce local recurrence and improve survival rates in patients with rectal carcinoma. This paper reports the problems that have arisen with the introduction of this new surgical technique.

Methods This was a prospective study of two consecutive groups of patients: one who underwent TME ($n = 76$) and one who did not (non-TME, $n = 76$).

Results Postoperative mortality rate in the non-TME and TME group was 5 and 7 per cent respectively, and the rate of anastomotic failure was 8 and 16 per cent respectively. Anastomotic leaks in TME patients were located in the mid and lower rectum. TME patients with anastomotic failure had lower anastomoses and a longer duration of operation than non-TME patients. Intraoperative problems were encountered in 71 per cent of the failures. All TME patients who had a leak required reoperation compared with 25 per cent of non-TME patients. TME patients without postoperative complications stayed significantly longer in hospital than non-TME patients.

Conclusion Anastomotic dehiscence increased after introduction of the TME technique but this improved with experience.

Rectal cancer in Norway has increased from 6·5 per 100 000 population in 1953 to 15 per 100 000 in 1992, and is expected to reach 21·5 by 2012[1]. The reported incidence of local recurrence after radical resection varies widely between 2·6 and 32 per cent[2]. In a Norwegian survey carried out between 1986 and 1988, Norstein *et al.*[3] reported a local recurrence rate of 29 per cent in patients younger than 75 years after a median observation of 60 months. Only 38 per cent of patients could have a second radical resection. Radiotherapy, before and after surgery, has been shown to reduce local recurrence, but has no effect on 5-year survival rate[4]. Postoperative irradiation in combination with chemotherapy decreases local recurrence and increases survival[5–7], and is now standard adjuvant treatment for rectal cancer stages II and III in North America.

Total mesorectal excision (TME) was introduced as a new surgical technique for rectal cancer. Local recurrence rate after 5 and 10 years is reported to be less than 5 per cent in curative cases and 5-year survival rate is 80 per cent. This is much better than any comparable studies, even with adjuvant therapy[8–10].

In 1994 the authors introduced TME for rectal cancer in Ullevaal Hospital. The aim of this report is to audit the introduction of a new surgical technique with regard to changes in various operative parameters, postoperative morbidity and mortality.

Patients and methods

Two groups of patients undergoing surgery for rectal carcinoma were prospectively compared (*Table 1*). Seventy-six consecutive patients (non-TME) had surgery between January 1992 and December 1993 before TME was introduced, using standard techniques[11]. The operations were performed by both trainees and senior surgeons.

In 1994 two senior surgeons were trained (by R.J.H.) in TME and, thereafter, participated in every subsequent operation to ensure proper technique[12]. Between January 1994 and December 1995, 76 consecutive patients underwent operation using TME. Until February 1995 a decision was made whether or not to use a diverting loop ileostomy. After that, faecal diversion became routine if the anastomosis was located below 13 cm.

In this paper the site of rectal cancer was defined according to International Guidelines for Cancer Registrars and The Cancer Registry[1] of Norway; i.e. 7 cm or less from the anal verge, low rectum; over 7 cm but less than or equal to 12 cm, mid rectum; over 12 cm but less than or equal to 20 cm, upper rectum.

All patients received antithrombotic therapy before surgery (Macrodex; Medisan AB, Uppsala, Sweden) and antibiotic prophylaxis (doxycylin 400 mg and metronidazole 1500 mg intravenously before operation).

Table 1 Clinical details

	Non-TME	TME
No. of patients	76	76
Sex ratio (men:women)	40:36	34:42
Mean (range) age (years)	69·6 (36–91)	67·9 (37–90)
Dukes stage		
A	13 (17)	18 (24)
B	30 (39)	30 (39)
C	16 (21)	12 (16)
'D'	9 (12)	8 (11)
Miscellaneous*	8 (11)	8 (11)
Abdominoperineal resection	22 (29)	28 (37)
Low anterior resection	53 (70)	44 (58)
Hartmann's operation	1 (1)	4 (5)

Values in parentheses are percentages. *Miscellaneous diagnoses included ten adenomatous lesions (three total mesorectal excision (TME), seven non-TME), four villous adenomas presumed malignant (three TME, one non-TME) and two anal carcinomas (both TME)

Paper accepted 3 July 1997

Statistical analysis

Differences between the two groups were measured by contingency tables (χ^2 test). Comparisons with reference to continuous parameters were carried out using the Student's t test. Statistical significance was accepted at $P \leq 0·05$.

Results

The distance from anal verge to rectal tumour was lower in patients who had undergone abdominoperineal resection (APR) who had TME than in non-TME patients (3·1 *versus* 5·4 cm, $P = 0·004$). There was no difference in this distance in patients who had low anterior resection (LAR) (non-TME 11·6 cm; TME 11·4 cm).

The distance from the anal verge to the anastomosis in patients who had LAR was significantly less in the TME group (6 cm) than in the non-TME group (7·1 cm) ($P < 0·03$).

Operative details

TME operations were shorter than non-TME operations (mean 176 *versus* 186 min), both for APR (mean 188 min for TME *versus* 211 min for non-TME) and LAR (mean 169 min for TME *versus* 176 min for non-TME).

There were no significant differences in mean blood loss between non-TME and TME operations either after APR (1213 *versus* 1269 ml) or LAR (887 *versus* 973 ml).

Intraoperative perforation of the rectum was evident in 29 per cent of non-TME patients and 16 per cent of TME patients. Perforations were more common during APR (non-TME 59 per cent *versus* TME 32 per cent) than LAR (non-TME 13 per cent *versus* TME 7 per cent). All APR perforations were located in the anal canal and only occurred in low-placed tumours in the LAR group (non-TME 8 cm *versus* TME 3·8 cm).

Complications

There were no significant differences in the number of patients with complications (*Table 2*), or in the number of complications per patient (non-TME 2·18 *versus* TME 2·73). In-hospital mortality rates were 5 and 7 per cent in the non-TME and TME groups respectively. Anastomotic dehiscence (non-TME one; TME three) and cardiopulmonary complications (non-TME three; TME two) were the causes of postoperative death.

Table 2 Complications

	Non-TME	TME
Complications		
Total	34 (45)	40 (53)
APR	11 (50)	20 (71)
LAR	23 (43)	19 (43)
Mortality		
Total	4 (5)	5 (7)
APR	1 (5)	0
LAR	3 (6)	4 (9)
Anastomotic dehiscence	4 (8)	7 (16)
Reoperation required	1 (2)	7 (16)*
Level of anastomosis (cm)		
With anastomotic dehiscence	6·8	4·7
Without anastomotic dehiscence	7·4	5·9

Values in parentheses are percentages. TME, total mesorectal excision; APR, abdominoperineal excision of the rectum; LAR, low anterior resection. *$P = 0·05$, χ^2 test

Table 3 Number of patients with complications according to the distance of the tumour from the anal verge

	Non-TME ($n = 53$)	TME ($n = 44$)
Upper rectum	6 (30)	6 (40)
Mid rectum	12 (46)	6 (33)
Lower rectum	4 (57)	8 (73)

Values in parentheses are percentages. TME, total mesorectal excision

There were more patients who underwent APR with postoperative complications in the TME than in the non-TME group (*Table 2*). Patients with lower tumours had more postoperative complications than patients with higher tumours (*Table 3*).

All patients in the TME group with leaks underwent reoperation compared to only one in the non-TME group (*Table 2*). Mean time from operation until the leak was diagnosed was 8 (range 4–15) days in the TME group, and the mean time from first symptom of leak to reoperation was 1 day (range 6–48 h). Three of the patients with TME and a leak died.

TME patients without faecal diversion had a higher incidence of anastomotic leakage (25 per cent) than those defunctioned (8 per cent). From February 1995 faecal diversion became routine after LAR and since then there has been no leak in 31 further operations (*Fig. 1*). The anastomoses were lower in patients with leaks in the non-TME as well as in the TME group (*Table 2*). Tumours in TME patients with a leak were located either in the low ($n = 4$) or mid ($n = 3$) rectum.

Operating time in TME patients with anastomotic failure was significantly longer than in patients without (193 *versus* 164 min, $P = 0·035$) and it was also longer than in patients with other complications (193 *versus* 177 min). This could be explained by significant intraoperative problems in five of the seven patients with an anastomotic leak.

There were no correlations between anastomotic failure and ligation of the ascending left colic artery, mobilization of the splenic flexure, distribution of American Association of Anesthesiologists (ASA) scores or

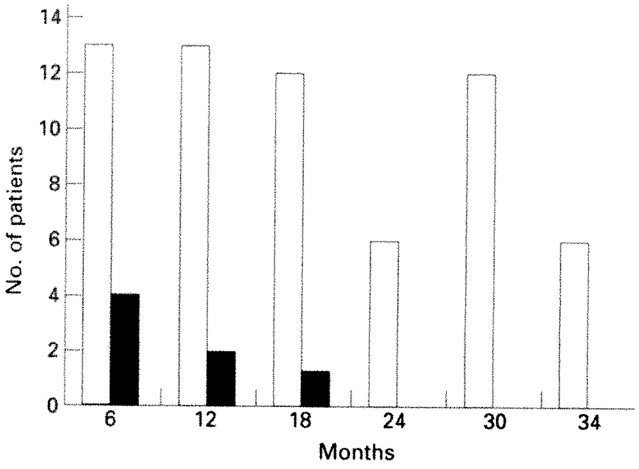

Fig. 1 Occurrence of anastomotic dehiscence in low anterior resection (LAR) with total mesorectal excision during 34 months. □, LAR; ■, leak

additional diseases (two had cardiac problems, one had cardiac problems and diabetes). The seven anastomotic failures were equally distributed among four surgeons.

Hartmann's operation

Two patients who had Hartmann's operation and TME developed complications. One patient died on the 6th day after operation from a cardiac arrest.

ASA score and complications

There was no difference in the distribution of ASA scores between non-TME and TME patients (data not shown). In the non-TME group there was an increase in complications with increasing ASA score (ASA I, 25 per cent; ASA III, 78 per cent). This was not seen in the TME group (ASA I, 54 per cent; ASA III, 59 per cent).

Postoperative stay in hospital

Patients with postoperative complications stayed significantly longer in hospital than those without (non-TME, 21·7 *versus* 9·4 days, $P<0.001$; TME, 19·2 *versus* 12·9 days, $P=0.002$). TME patients without complications stayed significantly longer in hospital than non-TME patients (TME, 12·0 days; non-TME, 9·4 days, $P<0.001$).

Discussion

In patients with primary rectal cancer the rectum and mesorectum is increasingly regarded as a single unit of regional disease to be resected *en bloc* by TME[10–13]. The introduction of a new operative technique may, however, influence postoperative morbidity and mortality.

As reported by others[14,15], postoperative complications occurred in 50 per cent of both groups. The number of complications per TME patient was higher than that per non-TME patient. This may be explained by more anastomotic failures after TME. As also reported elsewhere[16], complications were more frequent after APR than LAR in patients with low tumours. Presently, the authors perform a partial mesorectal excision for tumours above the peritoneal reflection, taking 5 cm of the rectum and mesorectum distal to the tumour.

The postoperative mortality rate was in accordance with some reports[8,14], but higher than in others[13,15]. One explanation may be that patients in this series were older. Anastomotic leakage was the most important cause of postoperative death in LAR patients who had TME[15–18]. Leaks after TME occurred between the 4th and 15th days after operation and, with one exception, all were diagnosed and operated on within 24 h of the onset of symptoms. Time to operation in those who died was even shorter (between 12 and 24 h). It seems unlikely that a routine contrast enema could have quickened diagnosis and thus reduced mortality.

The advantage of a defunctioning stoma has been reported by Karanjia *et al.*[18]. In the present study no clinically significant anastomotic leak has been seen in 31 consecutive LAR operations since faecal diversion became routine. All previous leaks occurred in patients with low anastomoses, and tumours located either in the mid or lower rectum[17].

The longer duration of operation, and observation of intraoperative incidents in five of seven TME patients who leaked, strengthens the hypothesis of a relationship between surgical problems and anastomotic dehiscence. There was no correlation between leaks and ligation of the left colic artery or mobilization of the splenic flexure[17,19].

Use of the TME technique has been reported to decrease the number of APRs[8], but the opposite was observed. The distance from tumour to anal verge was significantly less in the TME group, indicating that the reason for more APRs was the referral of a group of patients with lower tumours rather than a change in technique. A significant reduction in the distance from the anal verge to the anastomosis was observed after LAR indicating a more complete removal of the distal mesorectum by TME.

TME usually increases the duration of operation[13,14], but there was an average reduction of 10 min in this study, probably because of the participation of an experienced surgeon at every operation.

Intraoperative perforation of the rectum may spill tumour cells and increase local recurrence[20–22]. Changing operative technique to TME reduced the rate of intraoperative perforation. Most were seen during anal dissection in APR. All leaks during LAR were in patients with big tumours in the lower rectum.

Since 1996 patients with a perforation have received postoperative radiotherapy. Preoperative radiotherapy is an alternative for locally advanced tumours.

As expected, patients with postoperative complications had a significantly longer hospital stay in both groups. However, patients with LAR and TME stayed longer in hospital than patients without TME. This may be explained by the more extensive use of faecal diversion after TME and the necessary adaptation of the patients to the use of stomal bags.

On the introduction of a new surgical technique it is important to record all complications for continuous evaluation. This study has confirmed that the introduction of lower anastomoses with TME increases morbidity and mortality, though these problems can decrease with experience. The present rate of complications makes TME an acceptable risk for surgery of rectal cancer. Routine faecal diversion appears to offer protection against the complication of anastomotic dehiscence.

Abdominal ultrasonography in the diagnosis of colonic cancer

N. G. B. RICHARDSON, A. G. HERIOT, D. KUMAR and A. E. A. JOSEPH*

Background Colonic cancer is normally diagnosed by barium enema or colonoscopy. Neither investigation is ideal, especially in the elderly patient. This study investigates the potential role of abdominal ultrasonography in the diagnosis of colorectal carcinoma.

Methods Fifty-four patients with known or suspected colonic carcinoma were referred for abdominal ultrasonography. A single radiologist performed scans on these patients and the site of any colonic mass or wall thickening considered to be consistent with a colonic carcinoma was reported. All carcinomas were confirmed by histology on tissue obtained at colonoscopy or surgery against which the ultrasonographic diagnosis was compared. Colonic masses detected in patients undergoing routine abdominal ultrasonography for abdominal symptoms were also reported.

Results Forty-five of the 54 patients referred had colonic carcinoma and abdominal ultrasonography detected 43 of the tumours and correctly identified the site of 41. The sensitivity, specificity and accuracy of abdominal ultrasonography in the detection of colonic tumours considered to be consistent with a colonic carcinoma was 96, 67 and 91 per cent respectively. Seven tumours were identified in patients referred before any other investigation had been carried out.

Conclusion Abdominal ultrasonography may detect a colonic mass or wall thickening consistent with a colonic carcinoma with a high degree of accuracy and may be useful when barium enema or colonoscopy is not possible.

Colonic neoplasia is traditionally diagnosed by either barium enema or colonoscopy. Both of these investigations require unpleasant and sometimes intolerable bowel preparation, are invasive and have a recognized failure rate. In frail and elderly patients these tests cause significant distress and are often unsuccessful. Computed tomography has been reported as an alternative, less invasive investigation in such patients[1]. This paper reports experience of abdominal ultrasonography as an investigation in the detection of colonic cancer.

Patients and methods

To test the accuracy of abdominal ultrasonography in detecting colorectal carcinoma, 54 patients (25 men, 29 women) with known or suspected colorectal carcinoma were referred for abdominal ultrasonographic examination, which was performed by a single consultant radiologist with a particular interest in ultrasonography. Forty-five of the 54 patients had already been investigated by barium enema or colonoscopy and the remaining nine patients had undergone no colonic investigation before referral. The radiologist was blinded to these results and reported the site of any colonic mass or wall thickening that was considered to be consistent with a colonic carcinoma and whether liver metastases were visible. No patients with rectal tumours identified on rigid sigmoidoscopy were referred and all patients either had a colonoscopy or surgery as the 'gold standard' investigation against which the ultrasonographic diagnosis was compared.

Abdominal ultrasonography was performed using either an Aloka 650 machine with 3·5-MHz frequency probe (Keymed, Southend-on-Sea, UK) or an ATL (HDI) machine with a C 4-2 broadband width probe (Arden Press House, Letchworth, UK). A routine abdominal scan was undertaken with the addition of views of the oesophagus, stomach and the entire colon where technically feasible. Limited views of the rectum were undertaken as it was felt that this area could be viewed satisfactorily with a rigid sigmoidoscope. The features used to identify colonic cancer in this study are shown in *Figs 1–3*.

The radiologist routinely performed these additional views on all patients referred for abdominal ultrasonography for investigation of abdominal symptoms of unknown origin (usually referrals from general practitioners), and reported any colonic mass or wall thickening detected.

Results

Forty-five of 54 patients referred had colonic carcinoma confirmed histologically on samples obtained at surgery or at colonoscopy. The results of abdominal ultrasonography in detecting colonic carcinoma are shown in *Table 1*. The sensitivity of abdominal ultrasonography in detecting colonic carcinoma was 96 per cent, specificity 67 per cent and accuracy 91 per cent. The positive predictive value was 93 per cent and the negative predictive value was 75 per cent. Twelve patients with a true-positive ultrasonographic diagnosis had liver metastases identified on ultrasonography. One with a false-positive ultrasonographic diagnosis had liver metastases identified on ultrasonography; the patient was later found to have adenocarcinoma of the lung.

The site of the colonic tumour was incorrectly identified by ultrasonography in two patients (one sigmoid cancer was diagnosed as caecal and vice versa). There were two false-negative diagnoses: in one patient a locally advanced caecal cancer was diagnosed as ileocaecal tuberculosis and in another no tumour mass was identified. The stage of the tumour detected by ultrasonography in patients who had surgery was T_2 (four patients), T_3 (35) and T_4 (two).

Published in part in abstract form as *Gut* 1996; **38**(Suppl 1): A67
Paper accepted 14 August 1997

The tumour stage in the two patients with a false-negative ultrasonographic diagnosis was T_2 and T_3.

Barium enema missed sigmoid colon cancers in four patients because of diverticular disease and in all of these the lesion was diagnosed at ultrasonography. In one patient barium enema reported a caecal tumour as being in the sigmoid colon. In this case ultrasonography correctly identified a caecal cancer. In another patient who had a barium enema reported as normal 18 months previously, three colonic cancers were identified on abdominal ultrasonography. These were confirmed at a subsequent barium enema and then operation.

In addition, during routine abdominal ultrasonography performed for investigation of patients with abdominal symptoms of unknown origin, ten patients (five male, five female) had colonic masses identified which were considered to be consistent with colonic carcinoma. None of these patients had undergone any previous investigations and the diagnosis of colonic carcinoma was confirmed histologically in all ten patients. It is not possible to give a value for the accuracy of ultrasonography in the diagnosis of colonic carcinoma in this group of patients undergoing routine abdominal ultrasonography as the number of false-negative diagnoses is unknown. However, so far no patient who has had a

negative result on abdominal ultrasonography has subsequently been diagnosed as having a colonic carcinoma.

Discussion

Ultrasonography has been reported as being accurate in the diagnosis of several colonic conditions[2] including the site and nature of obstructing lesions[3], colitis[4], diverticulitis[5] and cancer[6,7]. Ultrasonography has been used as a screening procedure for abdominal pathology by attempting to demonstrate thickening or other modifications of the colonic wall[8] with high specificity (93 per cent), but only moderate sensitivity (77 per cent). In this study, high sensitivity and moderate specificity was achieved for identification of a colonic mass or wall thickening consistent with a colonic carcinoma. This was with a selected patient group, the majority of whom had colorectal carcinoma but these data demonstrate a much higher detection rate than was achieved in a previous study on a similar patient group where only half the tumours were detected[9]. The radiologist was unaware of the diagnosis in each patient and routinely scanned the entire colon if possible. It was also possible to detect colonic carcinomas in individuals undergoing routine abdominal ultrasonography for investigation of symptoms of unknown origin in whom there was no prior suspicion of colonic cancer.

Abdominal ultrasonography is operator dependent and the radiologist involved was experienced. Accordingly these results are likely to be at the better end of the spectrum if variability between observers is considered. However, colonic views on ultrasonography are usually ignored and this technique could easily be taught to less experienced radiologists interested in ultrasonography to allow more general use with an acceptable level of accuracy. Operator experience is also applicable to the performance and interpretation of a barium enema or colonoscopy and performance of both improves with practice.

The ultrasonographic visualization of liver metastases is likely to increase the expectation of the operator of detecting a colonic tumour but as these are identified on the same examination, they act as a stimulus to search the colon more extensively. Ten patients had colonic tumours identified on routine abdominal ultrasonography for abdominal symptoms, confirming that this technique can detect colonic tumours in a less highly selected group of patients, although it is not possible to report sensitivity and specificity for this group. As regards tumour stage, the degree of resolution was enough to detect T_2 tumours without the need to use additional intraluminal fluid which has been used in previous reports[10,11].

Abdominal ultrasonography can detect colorectal carcinoma with acceptable accuracy but what, if any, should be its role as a diagnostic modality? Barium enema and colonoscopy are the usual methods of diagnosing colorectal cancer. The resolution provided by both is good and colonoscopy allows direct visualization and biopsy of any lesion identified. Both these investigations require bowel preparation which, especially in the frail elderly patient, may produce fluid and electrolyte imbalance and are often unpleasant and may even be intolerable. Barium enema may fail if the patient has insufficient sphincter control to retain the barium and can miss lesions, particularly in the sigmoid colon when associated with diverticular disease. Failure to detect lesions can occur in up to 15 per cent of cases, most commonly due to a failure in reporting rather than failure to demonstrate the lesion[12]. Total colonoscopy may be technically impossible even in the best hands and is only achieved reliably in 70 per cent of patients in all units[13]. Both investigations can result in bowel perforation, at a rate of one in 25 000 in the case of barium enema and one in 1700 in the case of colonoscopy[14]. Computed tomography has been suggested as an alternative investigation[15], but this is time consuming, expensive and exposes the patient to significant radiation. Recent work has been published[13] on 'virtual colonoscopy' which has the potential to image the colon non-invasively and with a high degree of accuracy, but this is currently experimental and availability is likely to be limited.

At present, the experience of ultrasonographic detection of colonic tumours is encouraging but it is not enough to replace barium enema or colonoscopy routinely. However, in cases where barium cannot be retained and it is impossible to pass the colonoscope round to the caecum, such as in elderly patients, the priority is to determine whether or not there is a carcinoma present in the bowel, and this may be achieved accurately with ultrasonography.

Conclusions

Abdominal ultrasonography can detect colorectal carcinoma with a high degree of accuracy. Ultrasonography is non-invasive and well tolerated by all patients and may have a role in diagnosing colorectal cancer, especially in frail or elderly patients.

Influence of blood components and faeces on the *in vitro* cancericidal activity of povidone–iodine

G. BASHA, F. PENNINCKX and P. YAP*

*Departments of Abdominal Surgery and *Hepatology, University Clinic Gasthuisberg, Catholic University of Leuven, Belgium*
Correspondence to: Dr F. Penninckx, Department of Abdominal Surgery, UZ Gasthuisberg, Herestraat 49, B-3000 Leuven, Belgium

Background Tumoricidal agents have been used to kill viable exfoliated tumour cells following colorectal cancer surgery. Recent *in vivo* experiments have thrown some doubt on the tumoricidal activity of povidone–iodine.

Methods The cytotoxic effect of distilled water and of povidone–iodine at 0·04, 0·4, 0·8, 2 and 4 per cent final concentrations on human SW620 colonic cancer cells in the presence of red blood cells, purified haemoglobin and red blood cell (RBC) membranes, plasma, albumin, faeces and bacteria was investigated. Cell viability was assessed using the trypan blue assay and MTT test.

Results The presence of albumin and plasma decreased the tumoricidal activity of povidone–iodine except for the highest concentration tested. Bacterial suspension did not influence the efficacy of povidone–iodine. Faecal material was found to have an intrinsic tumoricidal effect. Both intact and lysed RBCs very strongly inhibited the tumoricidal activity of all povidone–iodine concentrations tested. This inhibitory effect was due to haemoglobin, but not to RBC membranes.

Conclusions Low concentrations of povidone–iodine fail to kill all 'exfoliated' cancer cells in the presence of proteins, intact or lysed RBCs. Therefore, washing out of these organic materials before application of a relatively high povidone–iodine concentration (e.g. 5 per cent or greater) may be more useful in killing viable exfoliated tumour cells during surgery for colorectal cancer.

Three potential mechanisms have been proposed to explain local recurrence after 'curative' colorectal cancer surgery: incomplete primary tumour resection, metachronous carcinogenesis and implantation of viable exfoliated malignant cells[1]. The presence of viable free tumour cells in the intestinal lumen of patients with colorectal cancer, as well as the ability of these cells to proliferate and grow, have been documented[2–4]. Several tumoricidal agents have been used to eradicate these exfoliated cancer cells[5–9]. In non-randomized series of patients with colorectal cancer in whom intraoperative cytotoxic lavage of the resection margins was performed, low local recurrence rates have been observed[10–13]. Although the cancericidal ability of the antiseptic agent polyvinyl pyrrolidone–iodine (povidone–iodine) has been demonstrated *in vitro*[6,14], recent *in vivo* experiments have shed some doubt on the tumoricidal efficacy of this agent[15]. The presence of blood was found to inhibit the killing action of 1 per cent povidone–iodine on free tumour cells *in vitro*. It was suggested that several other 'organic materials' such as dietary residue, bacteria, mucus and proteins shed into the lumen might interfere eventually with the cancericidal effect of povidone–iodine.

In this study an investigation was made of the influence of bacteria, faecal material, albumin and blood components (intact and lysed red blood cells (RBCs), haemoglobin, RBC membranes and plasma) on the ability of various concentrations of povidone–iodine to kill human colonic cancer cells *in vitro*. These experiments have to be considered in the context of investigations on intraoperative preresectional orthograde whole-colon lavage using povidone–iodine to eliminate exfoliated tumour cells in patients with colorectal cancer.

Paper accepted 30 July 1997

Material and methods

Tumour cell suspension

SW620 human colonic carcinoma cells were grown in monolayer culture in 75-cm^2 flasks. The medium was minimum essential medium (MEM; Gibco, Life Technologies, Merelbeke, Belgium) supplemented with antibiotics (penicillin 200 units/ml, vancomycin 100 μg/ml, streptomycin 200 μg/ml, gentamicin 50 μg/ml, Amphotericin B 2·5 μg/ml), 10 per cent fetal calf serum and the following additives: L-glutamine 2 mmol/l, insulin 20 munits/ml and dexamethasone 50 mmol/l. SW620 cells are highly tumorigenic in immune-deficient mice[16,17]. After trypsinization with a 1 in 10 solution of trypsin ethylenediamine tetra-acetic acid (EDTA) in phosphate-buffered saline (PBS) (0·5 g trypsin, 0·02 g EDTA disodium salt dihydrate and 8·5 g sodium chloride per litre), cells were pelleted and resuspended in 10 ml MEM. Cell viability was assessed using the trypan blue exclusion test. The cell concentration was adjusted to about 10^6 cells per ml of tumour cell suspension.

Tumoricidal agents

The cytotoxic effects of the following agents were studied: distilled water, povidone–iodine (Belgana, Brussels, Belgium) 0·1, 1, 2, 5 and 10 per cent in distilled water. Some 4 ml of cytotoxic agent solution were added to 2 ml of tumour cell suspension and 4 ml of 'organic material' or its solvent (in parallel control tests). Thus, the final concentrations of povidone–iodine in these experiments were 0·04, 0·4, 0·8, 2 and 4 per cent, except for testing the effect of albumin (see below).

Assessment of tumour cell viability

Cell viability was assessed using the trypan blue exclusion test. The MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide) assay was used as a supplementary biochemical test to evaluate cell viability. Each mixture of tumour cell suspension, cytotoxic agent and 'organic material' or MEM (as a control) was centrifuged and resuspended in 1 ml of MEM after removing the supernatant. Samples (100 μl) of this resuspension were placed in each well of a multi-well plate and treated as described previously[9,18,19]. Multi-well plates were then placed in a scanning spectrophotometer (enzyme-linked immunosorbent assay reader) with a filter that absorbs wavelength 595 nm maximally. High readings correspond to high intensity of dye colour and thus to a high number of viable cells able to metabolize MTT salt. As the colour of the cytotoxic agent solutions, as well as the presence of dead cells or 'organic material', may influence the result, control (blank) tests were performed simultaneously. The cells in 2 ml tumour cell suspension samples, containing 10^6 cells, were 'killed' in the presence of 8 ml acetic acid 0·01 mol/l for 30 min. After centrifugation (150 *g* at 4°C for 6 min), the pellet was resuspended in 2 ml of medium and identical quantities of cytotoxic agent solutions and 'organic material' were added. After incubation for 30 min these mixtures were centrifuged and the pellet was resuspended in 1 ml of MEM. The MTT assay was then performed as described above. The absorbance observed for these control samples was subtracted from the readings obtained for test samples. When the difference was negative, it was considered to be zero.

Organic material

Bovine serum ablumin. For the study, 2·1 g bovine serum albumin (BSA) was dissolved in 24 ml cytotoxic agent solution. To 8 ml of this mixture 2 ml tumour cell suspension were added (7 per cent BSA final concentration) and incubated at 37°C for 30 min. After centrifugation at 150 *g*, 4°C for 6 min, the supernatant was discarded and the cell pellet resuspended in 1 ml MEM to assess cell viability. Parallel control tests were performed without BSA. All experiments were performed in triplicate.

Faeces. Some 21 g of faeces were obtained from a healthy volunteer, homogenized and mixed with 84 ml freshly prepared anaerobic reducing buffer (ARB; 0·1 mol/l sodium phosphate buffer, 0·01 per cent sodium ascorbate, 0·1 per cent sodium thioglycolate). Equal amounts of faecal slurry and cytotoxic agent were preincubated overnight at 4°C. After centrifugation, 8 ml of the supernatant (4 ml faecal slurry and 4 ml cytotoxic agent) were added to 2 ml of tumour cell suspension and incubated at 37°C for 30 min. After centrifugation the cell pellet was washed three times with MEM and resuspended in 1 ml MEM. In two parallel control series, ARB or physiological saline was used without faecal homogenate to assess the eventual interference of ARB with the tumoricidal effect of povidone–iodine.

Bacteria. Colonic bacteria consisted of *Bacteroides fragilis* 10^4 colony forming units (c.f.u.) per ml, *Escherichia coli* 10^3 c.f.u. per ml, *Clostridium perfringens* and *Eubacterium* 10^5 c.f.u. per ml, and *Enterococci* 10^2 c.f.u. per ml. These bacteria were grown in Bacto Fluid Thioglycollate Medium (Difco Laboratories, Detroit, Michigan, USA) with a final pH of 7·1 at 25°C. The mixture was stored at 4°C and placed at room temperature 24 h before an experiment. In the test series, a mixture of 2 ml tumour cell suspension, 4 ml cytotoxic agent and 4 ml bacterial suspension was incubated for 30 min at 37°C. Incubation was stopped by centrifugation (150 *g* at 4°C for 6 min) and the cell pellet was resuspended in 1 ml MEM. In two parallel control series, thyoglycolate medium or physiological saline was used without bacteria to assess the eventual interference of thyoglycolate medium with the tumoricidal effect of povidone–iodine. All experiments were performed in triplicate.

Blood. The effects of intact and lysed RBCs, RBC membranes, haemoglobin and plasma (fresh frozen plasma) were studied. Fresh packed cells (not older than 5 days) were used: 56 ml of packed cells were mixed with 28 ml of physiological saline. In the test series, mixtures of 2 ml tumour cell suspension, 4 ml cytotoxic agent and 4 ml packed cells were incubated for 30 min at 37°C, followed by centrifugation (150 *g* at 4°C). The cell pellet was resuspended in 10 ml of RBC lysing buffer (RBCLB; Sigma, Bornem, Belgium; 0·83 per cent ammonium chloride in 0·01 mol/l Tris buffer) for 1 min and centrifuged (50 *g*, 4°C for 6 min). These steps were repeated five times to wash out the RBC membranes. Finally, the remaining tumour cell pellet was resuspended in 1 ml MEM and assessed for cell viability. In a pilot study (three tests), RBCLB was shown not to affect tumour cell integrity as assessed by the trypan blue exclusion test. All experiments were performed in triplicate.

Haemoglobin and RBC membranes were prepared as follows. The same amounts of packed cells and physiological saline as used for the study of intact RBCs were lysed by freezing at − 80°C (overnight) and thawing at 42°C for 1 h. This freeze–thawing procedure was repeated and complete RBC lysis was confirmed microscopically. Lysed RBCs were centrifuged at 20 000 *g*, 4°C for 30 min, to spin down the membranes. This procedure was repeated up to five times until the supernatant was colourless. All supernatant was collected (and stored at 4°C) and freeze-dried for 24 h. The resulting haemoglobin powder was resuspended in 84 ml PBS and the haemoglobin content was shown to be similar to the original value before freezing. The pellet containing the RBC membranes was washed with physiological saline and centrifuged (20 000 *g* at 4°C for 6 min). After five washings, the membranes were resuspended in 84 ml of MEM. In the test series 2 ml of tumour cell suspension were mixed with 4 ml of cytotoxic agent and 4 ml of either membrane or haemoglobin suspension. Again, control series were performed in parallel experiments using 4 ml of MEM or 4 ml of PBS instead of the membrane or haemoglobin suspensions. All experiments were performed in triplicate.

Plasma. Some 12 ml of fresh frozen plasma were preincubated with 12 ml of each cytotoxic agent under study. To 8 ml of this mixture 2 ml of tumour cell suspension were added and incubated at 37°C for 30 min. After centrifugation at 150 *g*, 4°C for 6 min, the supernatant was discarded and the cell pellet was resuspended in 1 ml MEM to assess cell viability. Parallel control tests were performed using physiological saline instead of plasma. All experiments were performed in triplicate.

Statistical analysis

The data are presented as mean(s.d.). The Wilcoxon signed rank test was used for paired comparisons. Spearman's rank correlation was used to assess the relationship between variables determined by two different methods. $P < 0·05$ (two tailed) was considered significant.

Results

Effect of bovine serum albumin

Seven per cent BSA did not affect tumour cell viability. The partial tumoricidal effects of distilled water or povidone–iodine 0·08 per cent (final concentration) were found to be increased in the presence of 7 per cent BSA: 64(4·7) per cent viable tumour cells in BSA-free distilled water *versus* 42(2·2) per cent in distilled water with BSA ($P < 0·05$), and 63(7·5) per cent in povidone–iodine 0·08 per cent *versus* 37·5(5·8) per cent in povidone–iodine 0·08 per cent with BSA ($P < 0·05$). In contrast, the presence of 7 per cent BSA decreased the tumoricidal activity of povidone–iodine for other concentrations tested; 27·6, 19·2 and 13·5 per cent of cells remained viable in the presence of 7 per cent BSA *versus* 1·8, 0 and 0 per cent in BSA-free povidone–iodine 0·8, 1·6 and 4 per cent respectively. Povidone–iodine at an 8 per cent final concentration could still kill all tumour cells.

Cell viability as assessed by trypan blue exclusion and MTT tests showed comparable results ($r_S = 0·91$).

Effect of bacteria

The presence of bacteria minimally affected tumour cell viability in the absence of cytotoxic agent. The presence of bacteria did not significantly influence the efficacy of distilled water or povidone–iodine in several concentrations, except for the lowest concentration tested, although the thyoglycolate medium protected tumour cells slightly against the action of povidone–iodine. Povidone–iodine at greater than 2 per cent concentration had a 100 per cent killing rate, either in the presence or absence of bacteria during incubation. The results obtained using the trypan blue method to assess the cell viability were similar to those with the MTT test ($r_S = 0{\cdot}94$).

Effect of faecal slurry

Faecal material, but not its solvent ARB, affected tumour cell viability significantly in the absence of cytotoxic agent. Faecal slurry significantly increased the tumour cell killing rate of distilled water or lower concentrations of povidone–iodine, although ARB is shown to protect tumour cells. The killing rates as determined by two methods were similar ($r_S = 0{\cdot}79$).

Effect of blood components

Both intact and lysed RBCs strongly inhibited the tumoricidal activity of povidone–iodine of all concentrations tested. At povidone–iodine 2 per cent final concentration, about 12 per cent of tumour cells remained viable. Povidone–iodine 4 per cent could not be tested because of the occurrence of precipitation. Again, observations made with both methods for assessing cell viability were similar ($r_S = 0{\cdot}87$).

To determine whether this inhibitory effect of RBCs was due to haemoglobin or to the RBC membranes, the experiments were repeated with the purified fractions. RBC membrane had no effect. In contrast, haemoglobin completely blocked the tumoricidal action of povidone–iodine, including the 2 per cent final concentration (*Fig. 1*). Povidone–iodine 4 per cent could not be tested because of precipitation.

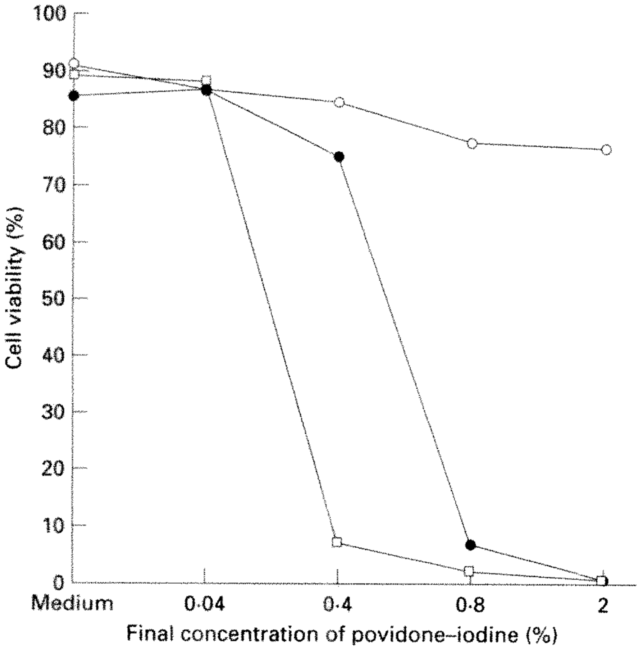

Fig. 1 Effect of haemoglobin (○), phosphate-buffered saline (●) and 0·9 per cent sodium chloride (□) on the tumoricidal activity of povidone–iodine as determined by trypan blue assay. Values are the mean of three tests

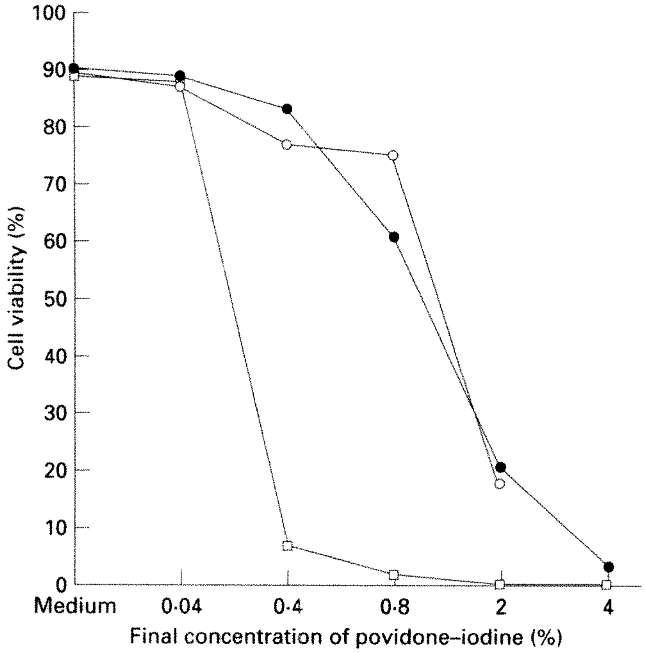

Fig. 2 Effect of intact red blood cells (○), plasma (●) and 0·9 per cent sodium chloride (□) on the tumoricidal activity of povidone–iodine as determined by trypan blue assay. Values are the mean of three tests

Plasma also inhibited the tumoricidal activity to the same extent as RBCs (*Fig. 2*). Both methods of assessing cell viability showed high correlation ($r_S = 0{\cdot}96$).

Discussion

Povidone–iodine is often used to irrigate the distal rectum or to perform on-table lavage preparation of the colon in order to allow a single-stage resection for colorectal cancer and anastomosis in the unprepared colon[20]. An antiseptic agent, it had also been shown to have tumoricidal activity on isolated or exfoliated viable tumour cells[6]. Recently, however, the suggestion was made that the tumoricidal efficacy of povidone–iodine may be blocked by the presence of organic material[15]. Normal stool contains about 80 g of soluble proteins per kg, but additional proteins may be secreted or released by colorectal cancer[21]. Also, significant amounts of blood might be present in the neighbourhood of the resection margins at the anastomosis or in the operative field.

Albumin is the most abundant serum protein present in stool of patients with colorectal cancer[22]. In the present experiments, albumin and serum proteins were shown to inhibit the tumoricidal activity of povidone–iodine as determined by two methods to assess cell viability. This inhibitory effect of proteins is thought to be due to the binding of iodine from povidone–iodine. High concentrations of povidone–iodine were able to saturate the binding sites of proteins, while retaining sufficient iodine to achieve a high killing rate.

Bacterial suspension was found not to interfere with povidone–iodine activity but was observed to have a moderate intrinsic tumoricidal activity. In contrast with bacteria, faecal material was shown to have a much higher degree of tumoricidal activity. Stool is known to contain considerable proteolytic activity that may arise from endogenous or microbial proteases[21]. This illustrates and explains the hostile character of the colonic content to exfoliated tumour cells.

Others have observed that blood affects the tumoricidal activity of povidone–iodine[15] or proflavine hemisulphate[23]. The present results indicate that lysed as well as intact RBCs inhibit remarkably the tumoricidal activity of povidone–iodine. In addition, free haemoglobin is the responsible component for the major inactivation of povidone–iodine by RBCs. In a pilot study, the authors found that povidone–iodine 2 per cent and 5 per cent can induce RBC lysis by as much as 3 and 12 per cent respectively, after incubation for 24 h.

In conclusion, povidone–iodine at a concentration of 2 per cent or more was confirmed to kill the selected tumour cells *in vitro*. However, organic materials, such as proteins (albumin at a concentration of 7 per cent or more, plasma), RBCs and, especially, free haemoglobin, were found to inhibit the tumoricidal activity of povidone–iodine. As the free iodine level is dependent on the concentration of the solution, dilute solutions of povidone–iodine have a smaller iodine reservoir and therefore less killing capacity. Consequently, removal of organic material might be beneficial in surgical practice, together with the use of a higher concentration of povidone–iodine (5 per cent or more) to achieve killing of all exfoliated tumour cells.

Histamine in human breast cancer

J. L. REYNOLDS, J. A. AKHTER, C. J. MAGAREY, P. SCHWARTZ, W. J. ADAMS and D. L. MORRIS

Background Histamine inhibits lymphocyte function *in vitro* at concentrations of greater than 10^{-6} mol/l. The aim of this study was to determine whether histamine concentrations in breast cancers were sufficient to produce an immunological effect.

Methods Tumour and adjacent normal breast content of histamine was measured using a radioenzymatic assay in 29 patients having surgery for breast cancer.

Results The median content of histamine in breast cancer tissue was 5·4 (range 0·9–27·3) μg/g (median concentration $4{\cdot}5 \times 10^{-5}$ mol/l), and was significantly greater than that in adjacent breast tissue ($P = 0{\cdot}007$).

Conclusion The concentration of histamine in breast cancer was sufficient to inhibit lymphocyte function and could be locally immunosuppressive.

There is evidence to suggest that histamine plays a significant role in cancer. Functional histamine receptors have been demonstrated in some tumour cell lines[1,2]. Histamine has also been implicated as a mediator of proliferation in breast cancer through its binding to novel intracellular receptors that are closely associated with antioestrogen binding sites[3]. Mast cells have been reported in high numbers around the periphery of various solid tumours and are known to be of prognostic value in colorectal cancer[4,5]. Specific inhibitors of the histamine synthesizing enzyme, histidine decarboxylase, have been shown to inhibit tumour growth in different animal models[6], and *in vitro*[7], suggesting that *de novo* synthesized histamine stimulates tumour growth. Other groups have found that histidine decarboxylase activity reflects the tumour mitotic index and is increased in human breast and colorectal cancer[8].

While histamine in physiological concentrations is an immunostimulant, it is thought to be immunosuppressive at high concentrations[9]. Histamine inhibits lymphocyte function[10,11] and has been reported to stimulate lymphocyte migration inhibitory factor at a minimum concentration of 10^{-6} mol/l[12,13]. A 40 per cent inhibition of phytohaemagglutinin-induced lymphoblastic response *in vitro* was achieved with a histamine concentration of 5×10^{-6} mol/l, and reversed by cimetidine[14]. Patients with colorectal cancer who were treated with a short course of cimetidine at the time of tumour resection had a 34 per cent trend to survival advantage at 3-year follow-up. Two other groups have recently reported on the survival of patients with colorectal cancer treated after operation with cimetidine[16,17]. Although there are important differences between these studies, all appear to show similar survival advantages[18]. A survival advantage has been demonstrated with cimetidine treatment in gastric cancer[19]. No clinical trials in breast cancer have been reported.

A significant increase of tumour infiltrating lymphocytes (TILs) was seen in patients with rectal cancer treated with cimetidine. Although histamine content in tumour tissue has been studied in animal models, few have examined the histamine content of human tumours. It is not clear whether the effect of cimetidine on TILs is related to histamine in tumours.

The aim of this study was to establish whether sufficient histamine was present in human breast cancers to affect lymphocyte activity.

Patients and methods

Specimens were taken from patients who formed part of a double-blind randomized clinical trial of adjuvant cimetidine treatment for breast cancer. This trial had been approved by the South Sydney Area Health Service ethics committee and informed consent was obtained from patients before treatment and investigations.

Tissue specimen preparation

Fresh tissue specimens, comprising tumour and adjacent healthy tissue, were chilled immediately on ice. Tumour tissue was always taken from the leading edge of the tumour. Specimens were chopped, weighed (average weight 300 mg), deproteinized in 2 ml of cold perchloric acid 0·1 mol/l and stored at −70°C until needed. On thawing, specimens were centrifuged at 3600 *g* for 15 min at 10°C and the supernatant was further diluted with water to minimize enzyme inhibition. The person performing the assay was blinded as to whether a specimen was tumour or adjacent tissue.

Histamine assay

The methods employed were those described by Henry *et al.*[20]. Each sample was assayed in triplicate, with and without a histamine standard. The concentration of histamine in the original specimen was expressed as micrograms of histamine per gram of fresh tissue weight. [^{3}H] *S*-adenosyl methionine and histamine-*N*-methyltransferase were purchased from Du Pont (Sydney, Australia).

Preliminary experiments were aimed at spiking various samples with known quantities of histamine to determine histamine retrieval, and to ensure the accuracy of the technique.

Histology

Routine pathology reports were used to access tumour histological type and differentiation. Staining for mast cells was carried out on 4-μm sections of formalin-fixed paraffin-embedded tissue from the tumour margin of 25 patients, using toluidine blue stain for mast cells, with which mast cell granules

Paper accepted 29 July 1997

stain deep purple. A positive control of skin tissue with pronounced mast cell infiltration was included in the staining run. For each tumour ten high-power (magnification × 400) fields were examined and mast cells counted; the mean number for the best six fields was then compared with tumour histamine content.

Statistical analysis

Individual specimens were analysed in parallel (tumour *versus* healthy tissue) with Student's t test. Collated specimens were analysed with the Wilcoxon test for non-parametric data.

Results

Twenty-nine patients with a mean(s.d.) age 60 (13) (range 31–83) years were studied. The majority of tumours were invasive ductal carcinomas ($n = 22$), one of which was a high-grade recurrent tumour. The remainder included invasive lobular ($n = 3$), cribriform ($n = 1$), mucinous ($n = 1$) and mixed ductal–lobular carcinomas ($n = 2$). One patient with invasive ductal cancer had Paget's disease of the nipple. Tumours were graded histologically according to the methods described by Bloom and Richardson[21].

Six of the 29 tumour specimens had no healthy breast tissue for comparison as insufficient tissue was available. Median(s.e.) histamine content in tumour tissue (5·4(1·3) μg/g) was significantly higher than in adjacent breast (1·3(0·4) μg/g) ($P = 0·007$, Wilcoxon test). Similarly, median histamine concentration was higher in tumour tissue (mean $4·9 \times 10^{-5}$ *versus* $1·2 \times 10^{-5}$ mol/l) (*Fig. 1*).

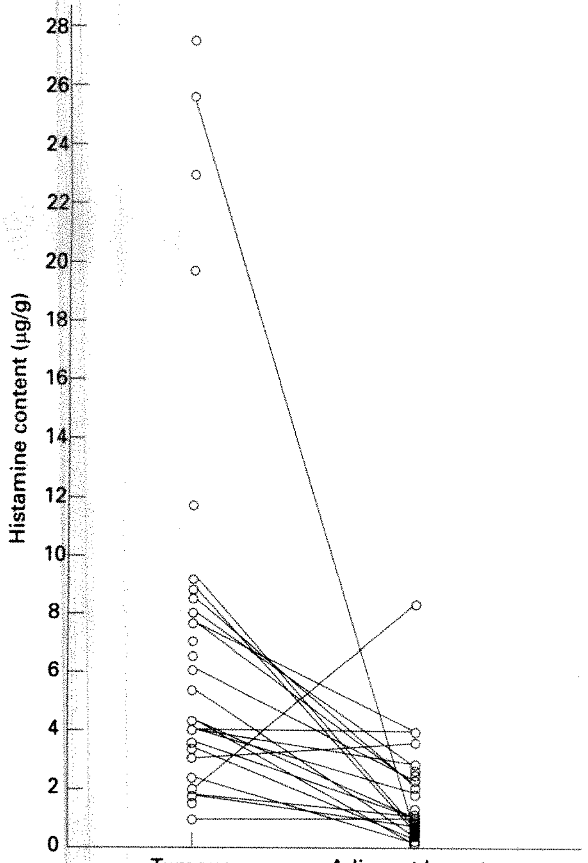

Fig. 1 Mean histamine content in breast cancer specimens: tumour tissue histamine ($n = 29$) compared with adjacent tissue ($n = 23$) from the same patient

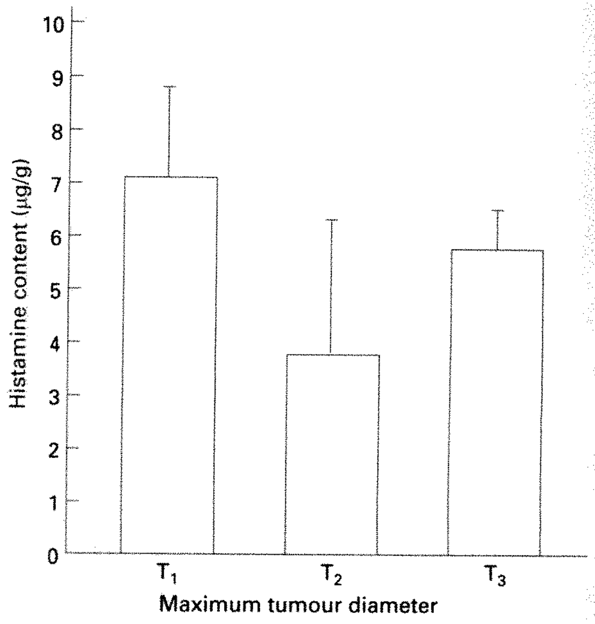

Fig. 2 Tumour tissue histamine content *versus* tumour size. Tumours were categorized according to maximum tumour diameter by the tumour node metastasis (TNM) classification: T_1, 2 cm or less ($n = 12$); T_2, more than 2 and less than 5 cm ($n = 13$); T_3, greater than 5 cm ($n = 4$). Values are median(s.e.). No significant correlation was found

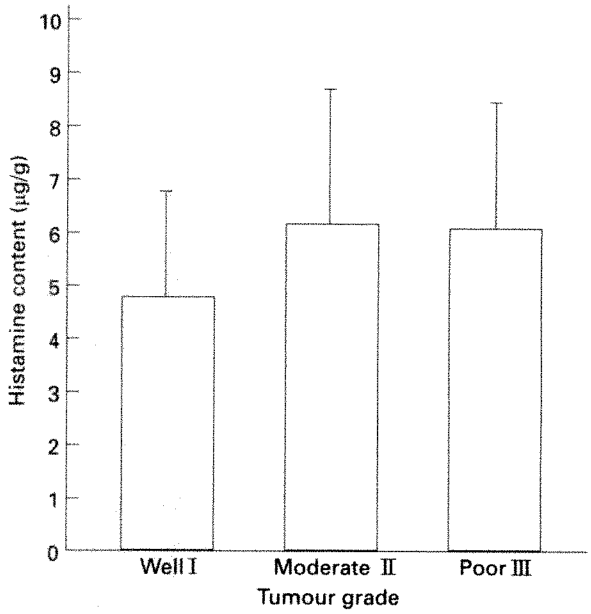

Fig. 3 Tumour tissue histamine content *versus* tumour histological grade. Histological grade was determined according to methods described by Bloom and Richardson[21]: grade I, low grade; grade III, high grade. Values are median(s.e.). Grade I, $n = 3$; grade II, $n = 13$; grade III, $n = 10$

Some 19 of 23 breast tissue specimens demonstrated a tumour tissue histamine content significantly greater ($P < 0·05$, Student's t test) than that of adjacent healthy breast tissue; only three had a tumour tissue histamine content lower than that of adjacent breast. All the tumour specimens had a histamine concentration greater than 1×10^{-6} mol/l. There was no difference in median(s.e.)

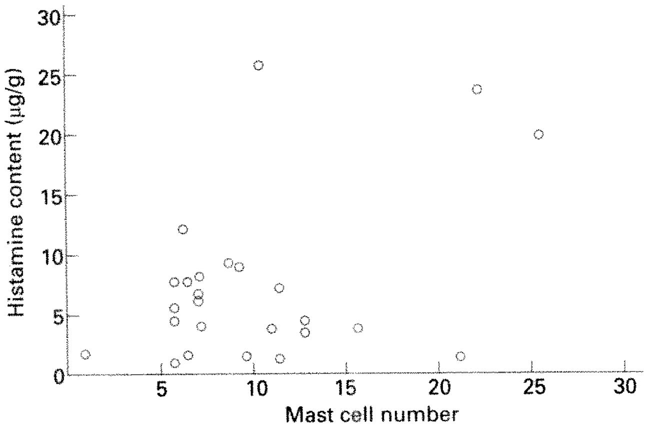

Fig. 4 Relationship between tumour histamine content and mast cell numbers (mean of six best fields) in breast cancer

histamine concentration between controls and patients taking cimetidine (6·5(4·4) *versus* 6·3(8·1) μg/g respectively). There was no correlation between tumour histamine content and tumour size (*Fig. 2*), grade (*Fig. 3*) or differentiation (data not shown). Similarly, there was no relationship between mast cell number (mean of six best fields) and histamine concentration ($n = 25$ tumours) (*Fig. 4*).

Discussion

This study demonstrates a significant difference between the histamine content of human breast cancers and of adjacent breast tissue. Cimetidine treatment did not affect tumour tissue histamine concentration, although it may increase the proportion of tumours with a prominent number of TILs. Similarly, Chanda and Ganguly[22] found median(s.e.) histamine content to be higher in breast tumour tissue (82·06(12·02) μg/g) than in adjacent healthy tissue (32·55(2·97) μg/g). These levels are considerably higher than those reported here, but the sample size was small ($n = 4$). García-Caballero *et al.*[3,28] found median(s.e.) histamine content to be lower in breast tumour tissue (4·05(27·0 μg/g) than in healthy tissue (6·10(0·46) μg/g), despite reporting a higher histidine decarboxylase activity in the tumour tissue. The range of histamine concentrations in the present study is in agreement with levels reported by García-Caballero *et al.*, although histamine content was significantly higher in breast tumour than in healthy tissue. It is possible that García-Caballero and co-workers found lower concentrations of histamine in tumour tissue because samples were taken from the centre of the mass[23]. It has been reported that histamine concentration is highest in the peripheral layer of actively growing tumour[24].

The high histamine concentration in breast tumours supports the hypothesis that histamine has an immunosuppressive effect. The correlation between histamine content and TILs, or the effect of cimetidine treatment and survival, is not yet known. Histamine content did not correlate with tumour size, grade or differentiation, which suggests that any relationship between histamine and tumour growth is complex. Tumour histamine levels in animal models can reflect the size of the tumour[6] suggesting that small, newly diagnosed tumours could synthesize more histamine than larger advanced tumours. The cellularity of tumour samples in this study would have been considerably higher than that of the surrounding breast tissue, which may explain the higher histamine concentrations present.

Histamine has an established immunosuppressive effect on lymphocyte proliferation at concentrations greater than 1×10^{-6} mol/l[10,12,13,25]. Khan *et al.*[26] also found that histamine concentrations between 10^{-8} and 10^{-4} mol/l suppressed the generation of class I-specific cytotoxic T lymphocytes. The effects of histamine on other parameters of lymphocyte function, such as migration, have not been fully established. Similarly, the effect of histamine on the various subsets of lymphocytes is not known. The relationship between histamine levels and TILs is likely to be complex, rendering its prognostic value controversial. Several groups have reported that a high density of lymphoreticular cells correlates with a favourable prognosis[27–30], whereas others have found no correlation at all[31,32]. In invasive ductal breast cancer, however, there is a positive correlation between the density of lymphoreticular cells and survival[27,28]. Lymphocytes infiltrating breast cancer have been shown to have a low level of natural killer cell activity[33], which might relate directly or indirectly to tumour histamine concentration.

The role of mast cells in breast cancer is also poorly defined. The mast cell stabilizing compound FPL 55618 inhibits rat mammary adenocarcinoma 13762NF by up to 70 per cent[34]. One report on mast cell density around breast tumour tissue concluded that high mast cell density (greater than 10 per mm^2 of stroma) correlated with improved survival; however, the survival curve from which the conclusions were drawn appeared to show the converse[35]. Some of the histamine measured in the breast tumours in the present study may have been released from mast cells at the time of tumour resection, although there was no correlation between mast cell number and histamine content in this study. There is good evidence to suggest that mast cell histamine plays a prominent role in tumour growth, but the source of the histamine has yet to be determined.

In conclusion, there are sufficiently high levels of histamine in breast cancers to inhibit lymphocyte activity.

Background Weight loss after total gastrectomy is a regular occurrence. Reconstruction with a gastric substitute has been suggested to facilitate recovery, but few randomized studies are available.

Methods In a randomized study comparing subtotal, total and total gastrectomy with an S-shaped pouch, 36 patients who had total gastrectomy with or without a pouch survived for more than 3 (mean 5·2) years. Body composition (four-chamber model, dual-energy X-ray absorptiometry, anthropometric data) was evaluated before operation, after 12 months and at long-term follow-up. Food intake was registered as a 4-day food record at 12 months and at long-term follow-up.

Results At long-term follow-up those allocated to the gastric substitute arm had lesser degrees of weight loss consisting mainly of the depletion of body fat stores, whereas lean body mass showed no significant decrease when adjusted for the process of ageing. There was no significant difference in food intake.

Conclusion Reconstruction with an S-shaped gastric substitute facilitates long-term recovery after total gastrectomy and should be considered when the prognosis is favourable.

Weight loss is a regular consequence of radical surgery for gastric cancer, irrespective of whether total or subtotal gastrectomy is performed[1–3]. Data have now been collected from controlled clinical trials to allow characterization of the effects of similar operations on nutritional intake as well as on body compartments during the first postoperative year[4]. The weight loss occurs during the first 3 months[1,3], whereafter weight stabilizes. Patients with a subtotal gastrectomy seem to consume somewhat fewer calories during the same period, after which their intake improves[3]. The construction of a gastric reservoir after total gastrectomy or leaving a gastric remnant after subtotal resection seems, however, not to improve the nutritional intake within the first 12 months after gastrectomy. Similarly, the mechanisms involved in weight development have been assessed by determining changes in body composition by use of total body potassium (TBK) content and total body water (TBW) calculations and thereafter estimating body cell mass (BCM), extracellular water (ECW), fat-free extracellular solids (FFESs) and body fat (BF). BCM seems to remain essentially unchanged over this limited time period in contrast to the BF compartment which decreases by 40 per cent during the first 6 months[4]. Concomitant with that, a significant decrease in triceps skinfold (TSF) thickness occurs, whereas only marginal changes in arm muscle circumference (AMC) and hand grip strength are observed[4,5]. These observations contrast, however, with reports in which the outcome of different gastric substitution techniques was assessed during somewhat different surgical clinical trial designs[5–8]. One important factor that has to be considered is that significant benefits of a certain reconstruction might not appear until a considerable time has elapsed after the actual operation.

Therefore, in the present study the long-term consequences of total gastrectomy on nutritional intake and body composition were determined with particular emphasis on the eventual beneficial effect of having a gastric substitute.

Paper accepted 19 December 1997

Patients and methods

A patient population was recruited into a controlled randomized clinical trial. Patients with distal carcinoma were randomized to subtotal or total gastrectomy with a simple Roux-en-Y oesophagojejunostomy, and those with more proximally located carcinoma to total gastrectomy with or without an S-shaped gastric substitute[3]. Details of the randomization are illustrated in *Fig. 1*. Data are now presented for the 36 patients who had total gastrectomy and a minimal follow-up of 3 (mean 5·2) years.

Subtotal gastrectomy

Fig. 1 Algorithm demonstrating the randomization and distribution of the originally enrolled patients. The 36 patients still alive after more than 3 years constitute the study population

]

During that time interval, 24 of the originally enrolled patients died from recurrent cancer, nine succumbed from other causes unrelated to the gastric carcinoma and six died during the first postoperative 6 months as described in detail previously[9]. Two additional patients were lost to follow-up because they refused to participate in any postoperative investigation. The operative procedures and preoperative and peroperative assessments have been reported in detail elsewhere[3,9].

Body composition was determined before operation, after 12 months and at the time of long-term follow-up by assessment of TBK content and TBW. TBK was determined by counting the 1·46-MeV γ radiation from the naturally present isotope ^{40}K, giving a standard deviation of approximately 80 mmol[10]. TBW was determined by isotope dilution of tritiated water. The coefficient of variation of a single TBW determination was 3·2 per cent[10]. In the four-compartment model used, body-weight (BW) is the sum of the four compartments: BCM, ECW, FFECSs and BF[10]. In this model the input variables are TBK, TBW, BW and normal body-weight (BW_{norm}). BCM is calculated where BCM (kg) = TBK (mmol) × 0·00833. Intracellular water is assumed to be 75 per cent of BCM; thus ECW = TBW − 0·75 × BCM. FFECSs are assumed as a constant fraction (12 per cent) of BW_{norm}. The BW_{norm} for each patient was taken from an adult control population[10]. BF is derived from the difference: BF = BW − (FFECSs + BCM + ECW). TSF thickness was measured with a Harpender caliper and AMC was calculated. Hand grip strength was measured before operation, after 12 months and at the end of the study. At follow-up, dual-energy X-ray absorptiometry (DEXA) (LUNAR DPX-L; Luna-Radiation Corporation, Madison, Wisconsin, USA) was also used to measure body composition[11].

Nutritional intake

Food intake was assessed and adjusted as reported previously[3], and a 4-day record was completed after 12 months and at the time of long-term follow-up. Food records were converted from household measures to gram weights and nutrient values by the use of national food consumption tables[12,13]. The weight of the main mean consumed each day was converted to decilitres (100 ml) to assess portion volume[3].

To validate further the recording of oral intake, faecal nitrogen losses (N_F) were measured together with urinary excretion of urea (N_U) over 3 days[14]. In all, information on these variables was acquired for 59 patients during the first 12 months. Dermal losses (N_D) were estimated to be 1 g/day[10,15]. Consequently, total protein losses were calculated from the formula $6{\cdot}25 \times (N_F + N_U + N_D)$ and then related to the reported protein intake at the different study points.

To compensate for changes in postoperative weight, food intake was also related to preoperative weight. This consideration was taken to circumvent the pitfall of having an undernourished but weight-stable postoperative patient reporting a false accurate food intake if calculated per kilogram of actual BW.

Statistical analysis and ethics

Analysis of the data was by the χ^2 test, regression analysis and Student's t test when applicable. $P < 0{\cdot}05$ was considered significant.

The study protocol was approved by the local ethics committee, and informed consent was obtained from each patient.

Results

The preoperative and peroperative characteristics of the patients and the histopathological features are detailed in *Tables 1* and *2*. At endoscopy, carried out at 12 months after operation and at the time of long-term follow-up, no oesophagitis or fibrous stricture of the distal oesophagus or oesophagojejunal area was observed. As reported previously[3], weight loss occurred early after gastrectomy and a weight of 10 per cent below the preoperative state remained at 1 year after operation (*Table 3*). When a paired analysis was carried out, total weight loss amounted to 10 kg compared with 1 kg ($P < 0{\cdot}01$) for patients having the Roux-en-Y and gastric substitute respectively, with the according percentage difference (*Fig. 2a*). From 12 months after operation and to the end of follow-up, patients with a substitute had gained 1 kg whereas those having a simple Roux-en-Y procedure had lost an additional 4 kg. However, when weight development was studied specifically in the time period from 3 to 10 years after operation, a cumulative increase in weight was observed in both groups of gastrectomized patients (*Fig. 3*).

5 years	5·9(0·4) (19)	6·5(0·5) (8)	6·1(0·3) (27)

Values are mean(s.e.m.) with number of patients in parentheses

Total energy intake at 1 year after gastrectomy was 8980 kJ and thereafter did not change with time (*Table 4*). It was not found that patients under-reported markedly, according to the cut-off score developed by Goldberg *et al.*[16]. There was no tendency towards larger food intake among those having a gastric substitute when this was related to the preoperative weight, but a trend existed towards larger maximal and mean portion sizes. When daily faecal energy losses were assessed years after gastrectomy, no significant difference was observed

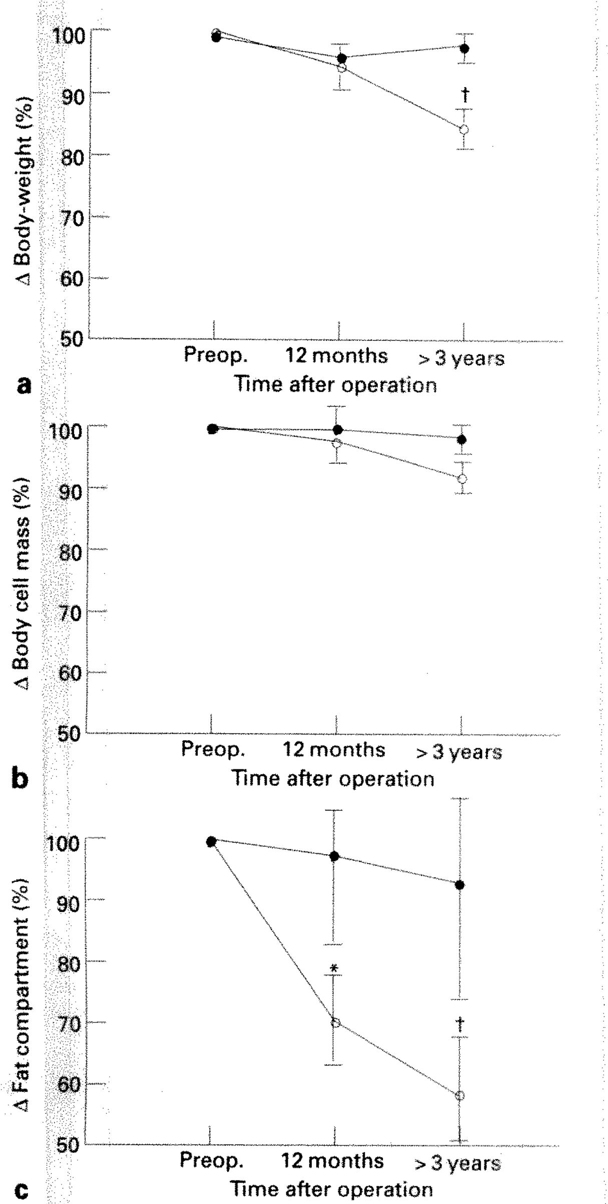

Fig. 2 Mean(s.e.m.) percentage changes of **a** body-weight and of (**b** and **c**) different body compartments compared with the preoperative state at 12 months and at long-term follow-up (mean 5·2 years). In **b** changes in body cell mass are given and in **c** changes in the fat compartment. ○, Patients with a simple Roux-en-Y reconstruction; ●, those with a gastric substitute. $^*P < 0{\cdot}05$, $^{\dagger}P < 0{\cdot}01$ (Roux-en-Y *versus* gastric substitute, Student's *t* test)

between the two study groups, but again numerically smaller losses were recorded in those having a gastric substitute (*Table 4*). When energy requirement was estimated based on basal metabolic rate curves[3,17], food intake in patients with a gastric reservoir slightly exceeded the calculated needs (42 kJ/day). Those with a simple Roux-en-Y oesophagojejunostomy had a calculated deficit of 419 kJ/day.

Protein intake was studied also in relation to the estimated losses. Higher protein intake was observed than the calculated losses, with a positive balance amounting to 6·5 g.

Parallel use of the DEXA scan and the four-compartment model to determine body compartments

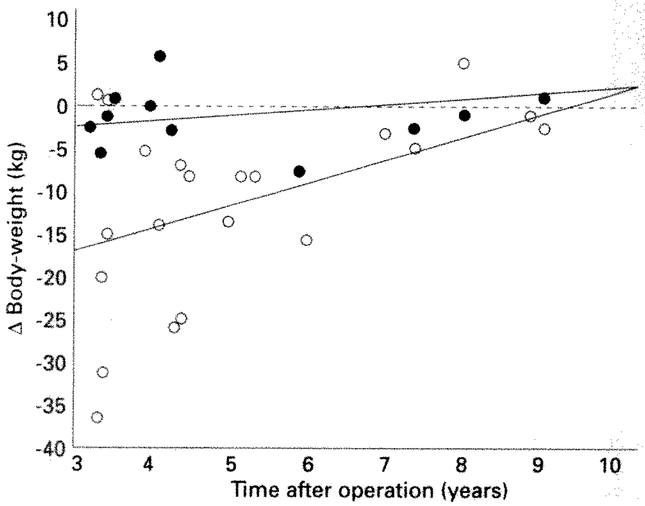

Fig. 3 Weight loss after operation in gastrectomized patients with or without a gastric substitute when assessed 3–10 years after operation. ○, Patients with a simple Roux-en-Y reconstruction; ●, those with a gastric substitute

revealed an excellent correlation with respect to both lean body mass ($r^2 = 0{\cdot}95$) and BF compartment ($r^2 = 0{\cdot}82$).

BCM, as assessed by TBK content, decreased significantly from preoperative values when re-estimated more than 3 years after gastrectomy ($P < 0{\cdot}0002$) (*Table 3*). However, when corrections were made for ageing and the associated natural decrease in lean body mass[10], this decrease in BCM from the preoperative value was not statistically significant (*Fig. 2b*). The fat compartment of the body decreased during postoperative follow-up ($P = 0{\cdot}01$) (*Fig. 2c*), a difference that became even more apparent when adjustment was made for the process of ageing. These observations were also corroborated by the recordings of TSF thickness, which decreased significantly from the preoperative value ($P = 0{\cdot}03$), but again AMC remained essentially unchanged over time. In parallel with the weight change, from 1 year after operation onwards, patients having a gastric substitute had an increase in TSF thickness of 1·2 mm, compared with an additional loss of 1·0 mm in those having a simple Roux-en-Y reconstruction when a paired analysis was carried out.

Discussion

One important factor behind the lack of consensus over the short- and long-term consequences of total gastrectomy and the impact of different reconstructive procedures is that very few controlled, clinical, randomized studies have been conducted and reported. Another explanatory factor might be that the period of observation after gastrectomy is of particular importance where the beneficial effects of, for instance, a gastric substitute become apparent only after a considerable period of time. This is illustrated by the present series in which a cumulative weight gain was observed many years after operation. In recent years some important observations have been published from trials with similar design[3,18,19], to which complementary information can now be added. Weight loss occurs after gastrectomy in the early postoperative period, whereafter BW seems to be quite stable. It should be noted that when the present patients were reassessed 5 years after total gastrectomy, marginal weight loss was found, but when the two study groups were compared specifically a significant difference emerged in favour of those having a gastric substitute, who had weight gain. These effects were recorded without any obvious change in BCM[4]. This profound reduction in the BF compartment was maintained throughout the years after gastrectomy, again with a recovery observed only in patients allocated to have a gastric reservoir. Furthermore, the data on TSF thickness paralleled these results on BF compartments with a corresponding increase from 12 months after operation onwards in patients with a gastric reservoir. The clinical consequences of these observations have to be studied and elucidated further. The impact of fat loss on, for instance, functional parameters such as endurance[20] is warranted.

The fact that a decrease in lean body mass was observed during long-term follow-up was somewhat contradictory to early postoperative observations. However, when these changes were assessed in relation to ageing, no significant effect remained. Again no significant alterations were recorded in AMC, supporting the very limited effects on lean body mass after similar operations. These observations may also be of importance from a more general perspective, when different outcomes are compared in studies of the nutritional and metabolic consequences of different operative interventions in an ageing study population.

What are the mechanisms behind this long-term difference in weight control between patients having a simple Roux-en-Y oesophagojejunostomy and a gastric substitute? Although no significant difference was observed in nutritional intake between the operative procedures, there was a tendency towards an intake of larger meals in the reservoir group. In the early postoperative period, the authors have previously found no difference in food intake between patients having a gastric reservoir and those with a simple oesophagojejunostomy. On the contrary, 3 months after gastrectomy the former group complained more frequently of difficulties in consuming adequate amounts of food[3]. Apparently, a process of adaptation seems to be operating. In addition, a tendency towards lower faecal losses of energy was recorded in patients with a gastric reservoir. Taken together, it is reasonable to assume that the most likely mechanism behind weight gain in these patients is a marginal but, from the long-term perspective, improved food intake to which is added a minimal reduction in energy losses. Whether factors such as emptying of food from the reservoir[21–23] are of significance has to be clarified.

An issue that has been focused on is the importance of the duodenal passage for the functional outcome after gastrectomy. The largest controlled study with the longest controlled clinical follow-up hitherto presented is that by Fuchs and co-workers[19], who demonstrated no beneficial effects of reconstructing the duodenal passage by a jejunal interposition in addition to a gastric pouch compared with the widely used and technically less demanding Roux-en-Y reconstruction. These authors concluded that differences between the two reconstruction principles might be documented by sophisticated functional assessments, but are probably of no major clinical importance. Although others have claimed opposing opinions[5,24–27], it has to be emphasized that there are inherent methodological problems in a single-institution study designed to evaluate a specific type of reconstruction which, in addition, has been developed at that institution.

It can thus be concluded that pouch reconstruction on a Roux-en-Y limb after total gastrectomy has long-term clinical advantages with respect to weight gain, which are probably the result of slight, but in the long-term perspective potentially important, differences in food intake and faecal energy losses. Therefore, in patients with a favourable tumour stage, which suggests a chance for long-term survival, pouch reconstruction after total gastrectomy ought to be considered seriously.

Background Adult respiratory distress syndrome and pneumonia remain a significant cause of morbidity and death following oesophagectomy. The aim of this study was to clarify the association between tumour necrosis factor (TNF) α and interleukin (IL) 1β with these pulmonary complications.

Methods The *in vitro* TNF-α and IL-1β producing capacity of peripheral monocytes with or without lipopolysaccaride (LPS) and serum level of IL-6 was measured in 19 patients with oesophageal cancer before and after surgery and in ten age-matched controls.

Results Six patients had raised TNF-α and IL-1β producing capacity of monocytes without LPS both before operation and on the day after surgery. In these patients plasma elastase and serum IL-6 levels subsequently increased while the ratio of arterial partial pressure of oxygen to fraction inspired oxygen decreased, and they developed bilateral lung infiltration on chest radiography on days 3–7. Five of the six developed pneumonia compared with none of the remaining 13 patients ($P < 0{\cdot}05$).

Conclusion Pulmonary impairment and pneumonia following oesophageal surgery was associated with raised monocyte producing capacity of TNF-α and IL-1β. These markers may be valuable in the preoperative assessment of patients awaiting oesophagectomy.

Operative procedures for oesophageal malignancy are becoming increasingly more radical and extensive[1,2]. Sepsis and multiple organ failure, mainly resulting from pulmonary complications and anastomotic leakage, are the major causes of postoperative death[3,4]. Acquired failure in the host immune defence mechanism is associated with such infections[5]. The authors previously reported postoperative pulmonary infections associated with deficiencies in cellular[6] and humoral immunity[7] as well as with increases in polyclonal immunoglobulin and acute-phase protein levels[8].

The pathological states induced by exaggerated secretion of either proinflammatory cytokines or systemic inflammatory response syndrome (SIRS)[9] are assumed to be associated with severe complications following oesophageal surgery. Septic shock and acute lung injury are not uncommon after operation. Tumour necrosis factor (TNF) α and interleukin (IL) 1β play a major role in the pathogenesis of SIRS[10,11]. These cytokines are produced mainly by monocytes[12,13] following surgical trauma or infection. The exaggerated secretion of TNF-α and IL-1β is mediated, in part, through the excessive induction of IL-8[14,15]. This activates neutrophils[16] to generate elastase[17] and reactive oxygen radicals[18], thus leading to tissue damage[14,15].

In the present study, to clarify whether TNF-α and IL-1β are associated with pulmonary impairment and pneumonia following oesophageal surgery, *in vitro* TNF-α and IL-1β producing capacity of peripheral monocytes as well as serum level of IL-6 were measured in patients undergoing transthoracic subtotal oesophagectomy.

Paper accepted 6 September 1997

Patients and methods

Patients

The study included 19 patients with squamous cell carcinoma of the oesophagus. There were 15 men and four women, of mean age 63 years (range 55–84) years. Seventeen had a one-stage operation in which an oesophagectomy and oesophageal reconstruction was done simultaneously. The remaining two had a two-stage operation in which an oesophageal reconstruction was done approximately 1 month after oesophagectomy[19].

The operation consisted of a total intrathoracic oesophagectomy and mediastinal lymphadenectomy carried out through a right thoracotomy. After returning the patient to the supine position, the stomach or colon was prepared for reconstruction and an abdominal lymph node dissection done through a laparotomy incision. Simultaneously, isolation of the cervical oesophagus and neck node dissection was conducted through a collar incision. Finally, the stomach or colon was brought up by way of the subcutaneous or substernal route and an anastomosis was performed in the neck. The lymph nodes that were removed included the paratracheal, hilar, tracheobronchial, pretracheal, subaortic, paraoesophageal, posterior mediastinal and diaphragmatic nodes in the mediastinum, pericardiac, lesser curvature and coeliac nodes in the abdomen and supraclavicular, deep cervical, paraoesophageal and paratracheal nodes in the neck. When a two-stage operation was performed, subtotal oesophagectomy, mediastinal node dissection and oesophagocutaneostomy were performed initially while oesophageal reconstruction along with a cervical and abdominal node dissection was done in the second stage. General anaesthesia was used in combination with a thoracic epidural (T7/8) in every patient.

Before operation, 13 patients with malnutrition received total parenteral nutrition and two with local cancer invasion to surrounding organs underwent radiation therapy. The stage of oesophageal cancer was estimated according to the fourth edition of the *TNM Classification of Malignant Tumours* of the Union Internacional Contra la Cancrum[20]. Ten healthy elderly volunteers (six men and four women; mean age 77 (range 69–82) years) served as controls.

Blood collection

Venous blood samples (30 ml) were taken and 2–3 ml whole blood was used for measuring routine blood parameters including leucocyte count and C-reactive protein (CRP) levels. The serum was separated and stored at − 70°C pending analysis of TNF-α, IL-1β and IL-6 levels. Cold-spun plasma was prepared in sterile tubes containing ethylenediamine tetra-acetic acid (EDTA, 0·34 mmol/l) and stored at − 70°C for an elastase assay. Some 20 ml heparinized blood obtained in a sterile tube was immediately used for monocyte preparation.

Monocyte isolation

The heparinized blood was overlayed on Ficoll–Hypaque (Pharmacia Biotech, Uppsala, Sweden) and centrifuged at 400*g* for 30 min. Interface cells were collected and washed three times at 200*g*, 4°C for 10 min in RPMI 1640 medium (Gibco, Grand Island, New York, USA) containing streptomycin 100 mg/ml. The cells were resuspended at $3–5 \times 10^7$ cells per ml in RPMI 1640 containing 10 per cent fetal calf serum (FCS; Gibco). The cells were allowed to adhere in a 100-mm plastic tissue culture dish (Falcon, Oxnard, California, USA) precoated with FCS. Non-adherent cells were removed by extensive washing with medium and adherent cells were obtained by treatment with 0·02 per cent EDTA for 15 min followed by gentle flushing in the presence of FCS. The purity of the adherent cell population, as assessed by non-specific esterase staining, routinely exceeded 95 per cent. The adherent cells were counted and the concentrations were adjusted to 5×10^5 cells per ml in medium with 10 per cent FCS and streptomycin.

Monocyte cytokine production

The adherent cells were dispensed into microtitre plates (Falcon, no. 3072) at a concentration of 1×10^5 cells per well in 200 ml of the same medium with FCS. The cytokine producing capacity of the monocytes was tested in a medium containing lipopolysaccaride (LPS) from *Escherichia coli* 0111; B4 L4130 (Sigma Chemical Company, St Louis, Missouri, USA) or in medium alone. To determine the LPS-induced cytokine producing capacity, LPS was added at a final concentration of 0·5 mg/ml. The plates with adherent cells were cultured for 24 h at 37°C in a humidified atmosphere containing 5 per cent carbon dioxide. Cell-free supernatants were collected and stored at − 70°C until testing.

Assay of tumour necrosis factor and interleukins

TNF-α and IL-1β were measured by enzyme-linked immunosorbent assay (ELISA) using commercially available human TNF-α and human IL-1β kits (Otsuka Pharmaceutical, Tokushima, Japan) while IL-6 was measured using a human IL-6 ELISA kit (Toray-Fuji Bionics, Tokyo, Japan). Each assay was performed in triplicate. The lower detection limit of the assay was 15 pg/ml for TNF-α and IL-1β, and 12 pg/ml for IL-6.

Assay of C-reactive protein and granulocyte elastase

Serum level of CRP was measured by rate immunonephelometry (automatic Immunochemistry Analyzer; Eiken Kagaku, Tokyo, Japan). Plasma level of granulocyte elastase was determined using a Merck Immunoassay PMN Elastase (Merck, Frankfurt, Germany).

Postoperative acute lung injury and pneumonia

Patients were managed using prophylactic mechanical ventilation in the intensive care unit for approximately 4–7 days following oesophagectomy. Their postoperative course was carefully monitored by regular analysis of blood counts, chest radiographs, sputum cultures and arterial blood gases. The criteria used for diagnosis of postoperative pulmonary complications[21] were as follows: (1) acute lung injury: ratio of arterial partial pressure of oxygen (PaO_2) to fraction inspired oxygen (FiO_2) less than 300 mmHg and bilateral lung infiltration on chest radiography; (2) adult respiratory distress syndrome (ARDS): PaO_2/FiO_2 less than 200 mmHg and bilateral lung infiltration; and (3) pneumonia: positive lung infiltration, fever above 38°C, leucocytosis above 10 000 per mm^3 and positive sputum culture.

Statistical analysis

Data were compared using either the unpaired Student's *t* test for continuous variables or χ^2 test (with Yates' correction or Fisher's exact test, as appropriate) for discriminant variables. Differences were considered to be statistically significant when the *P* value was less than 0·05.

Results

Preoperative monocyte cytokine producing capacity and serum cytokine levels

Mean(s.e.m.) TNF-α, IL-1β and IL-6 *in vitro* producing capacities of peripheral monocytes unstimulated with LPS (spontaneous producing capacity) in healthy age-matched volunteers were 21(7), 16(1) and 397(33) pg/ml respectively. For monocytes stimulated with LPS, the respective values were 4733(804), 6725(1116) and 129 254(13 730) pg/ml. TNF-α and IL-1β were not detected in the circulating venous blood. Serum level of IL-6 was 1·1(0·4) pg/ml.

In patients with oesophageal cancer, the spontaneous producing capacities of TNF-α (164(49) pg/ml), IL-1β (87(24) pg/ml) and IL-6 (13 989(1684) pg/ml) were significantly higher than those in the volunteers, while the LPS-stimulated producing capacities of TNF-α (6577(804) pg/ml), IL-1β (8535(906) pg/ml) and IL-6 (72 841(8371) pg/ml) were not. Serum IL-6 level (19(7) pg/ml) was also significantly higher in patients than in the healthy, age-matched volunteers ($P < 0{\cdot}01$).

Kinetics of monocyte cytokine producing capacities and serum cytokine levels

Fig. 1 shows the kinetics of the *in vitro* cytokine producing capacities of peripheral monocytes either unstimulated or stimulated with LPS, and serum IL-6 level following surgery. TNF-α and IL-1β spontaneous producing capacities were significantly raised on days 1–3 after operation and then recovered to preoperative levels on days 7–14. IL-6 spontaneous producing capacity was significantly reduced on postoperative day 1 and recovered thereafter. LPS stimulated producing capacity after surgery was raised for TNF-α but reduced for IL-6, similar to the spontaneous producing capacity; no changes were observed for IL-1β throughout the postoperative period.

TNF-α and IL-1β were not detected in the circulating venous blood after operation in any patient. Serum IL-6 was raised on days 1–7 after operation and then recovered.

Stratification of patients according to monocyte cytokine producing capacity

There was a statistically significant correlation between the spontaneous TNF-α and IL-1β producing capacities on day 1 after operation ($r = 0{\cdot}96$, $P < 0{\cdot}01$) (*Fig. 2*). Six patients had high producing capacities for these two cytokines. The patients were divided, based on their TNF-α and IL-1β spontaneous producing capacity the day after surgery, into two groups: six patients in group I with TNF-α 400 pg/ml or more and IL-1β 200 pg/ml or greater; 13 patients in group II with TNF-α less than 400 pg/ml and IL-1β less than 200 pg/ml. No correlation was found between the producing capacities of IL-6 and TNF-α or between those of IL-6 and IL-1β; nor was there a correlation between LPS-stimulated producing capacities.

Groups I and II were well matched for tumour staging and treatment (*Table 1*). The duration of operation and blood loss were similar in both procedures for the two patients who underwent a two-stage operation.

Comparisons of cytokine kinetics

Fig. 3 shows a comparison of the kinetics for TNF-α, IL-1β and IL-6 spontaneous producing capacities and serum IL-6 level between groups I and II. TNF-α and IL-1β producing capacities in group I were significantly higher than those in group II on admission ($P < 0.05$) and were also raised significantly on days 1–3 after operation ($P < 0.01$).

IL-6 monocyte spontaneous producing capacity and serum IL-6 was higher in group I than in group II on admission and after surgery. The difference for IL-6 spontaneous producing capacity of the monocytes was statistically significant on day 7 after operation, and for serum IL-6 on postoperative days 3–7, but not on admission or at any other time.

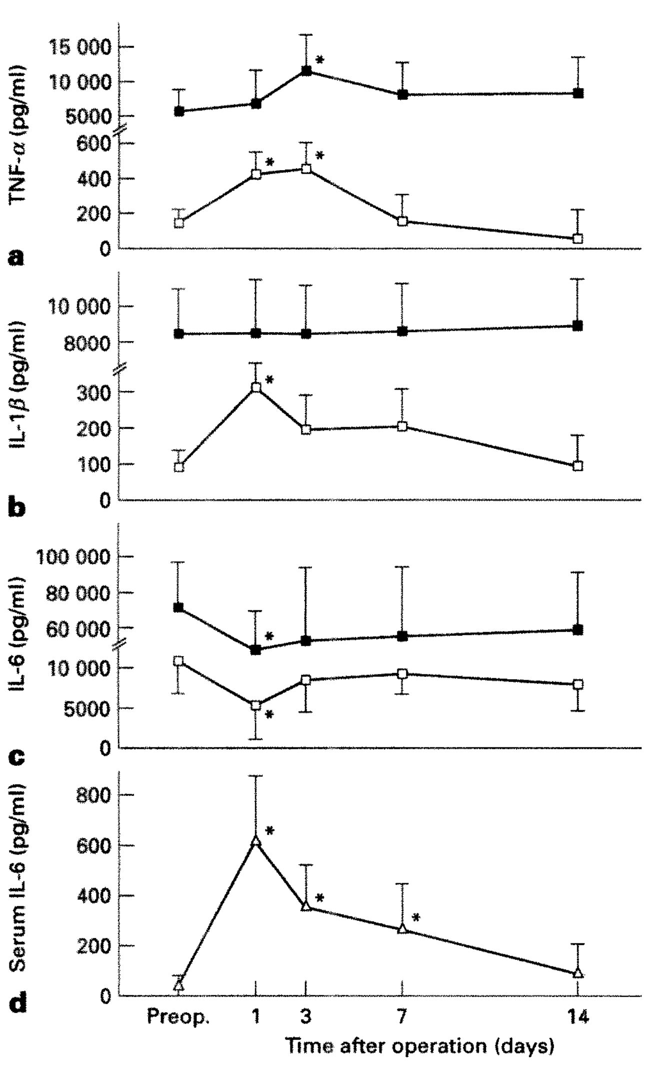

Fig. 1 Kinetics of cytokine producing capacities of monocytes (a–c) and of serum level of interleukin (IL) 6 (d) following oesophagectomy in all 19 patients, with (■) without (□) lipopolysaccharide. Values are mean(s.e.m.). TNF, tumour necrosis factor.* $P < 0.05$ *versus* preoperative level (Student's *t* test)

($r = 0.96$, $P < 0.01$)

Table 1 Comparison of clinical details in patients grouped according to monocyte cytokine producing capacity

	Group I (*n* = 6)	Group II (*n* = 13)
Age (years)*	65(2)	62(2)
Sex ratio (M:F)	5:1	11:2
Tumour length (cm)*	6·8(1·8)	4·4(0·5)
TNM stage		
0, I, II	3	6
III, IV	3	7
Pulmonary function*		
Percentage vital capacity	110(6)	100(5)
Percentage FEV$_1$	78·0(1·9)	80·8(1·8)
Preoperative TPN	4	9
Preoperative radiation	1	1
Operative procedure		
One stage	6	11
Two stage	0	2
Duration of operation (min)*	713(66)	649(42)
Operative blood loss (ml)*	1503(86)	1063(141)

*Values are mean(s.e.m.). Group I, excessive monocyte cytokine producing capacity; group II, cytokine producing capacity not increased. TNM, tumour node metastasis; FEV$_1$, forced expiratory volume in 1 s; TPN, total parenteral nutrition

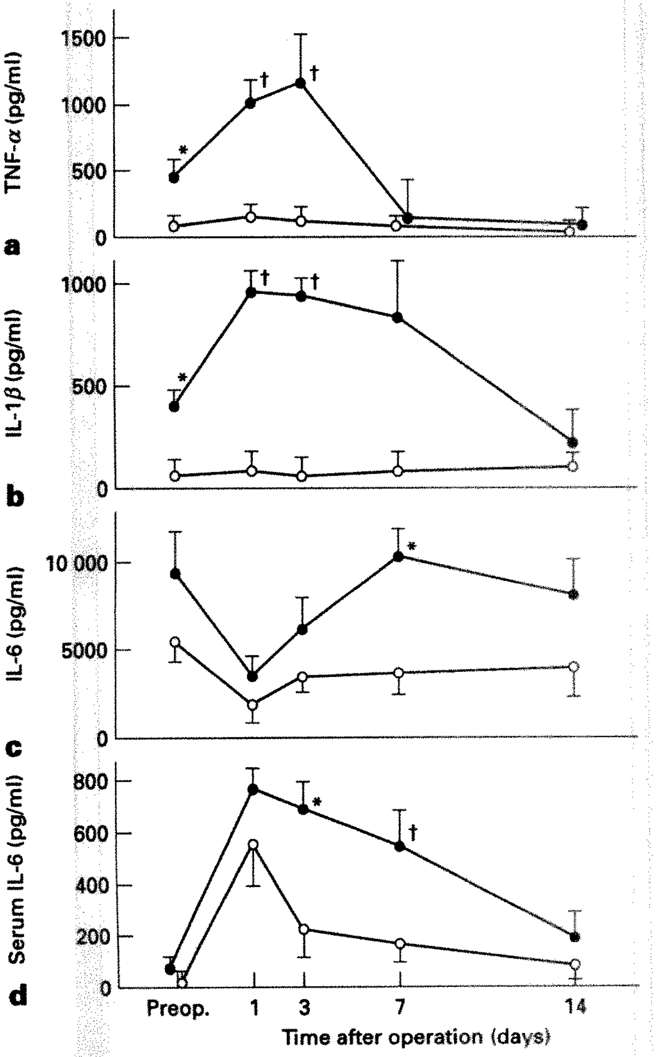

Fig. 3 Comparison of cytokine kinetics between group I (six patients; ●) and group II (13 patients; ○). a–c Spontaneous cytokine producing capacity of monocytes and d serum interleukin (IL) 6 level. Values are mean(s.e.m.). TNF, tumour necrosis factor. $^*P<0{\cdot}05$, $^\dagger P<0{\cdot}01$ *versus* group II (Student's *t* test)

LPS-stimulated monocyte cytokine producing capacities did not correlate with the spontaneous producing capacities. The TNF-α and IL-6 producing capacities were significantly depressed in group I compared with group II ($P<0{\cdot}05$) on admission and on postoperative days 1–7. In contrast, the IL-1β producing capacities were similar in both groups throughout the entire postoperative period (data not shown).

Plasma elastase, serum CRP and pulmonary kinetics

Fig. 4 compares kinetics of plasma elastase, serum CRP and PaO_2/FiO_2 following oesophagectomy in group I with those in group II. Plasma elastase level was raised on the day after operation and then recovered to preoperative level by day 14 in both groups. The level was higher in group I and significantly different from that in group II the day after surgery ($P<0{\cdot}05$). Serum CRP levels were raised after surgery but no significant difference was seen between the groups. PaO_2/FiO_2 decreased after surgery, but was lower in group I than in group II. The difference was significant 3 and 7 days after operation. PaO_2/FiO_2 reached a trough 7 days after operation in both groups. Mean PaO_2/FiO_2 was 203 mmHg in group I and 302 mmHg in group II on day 7.

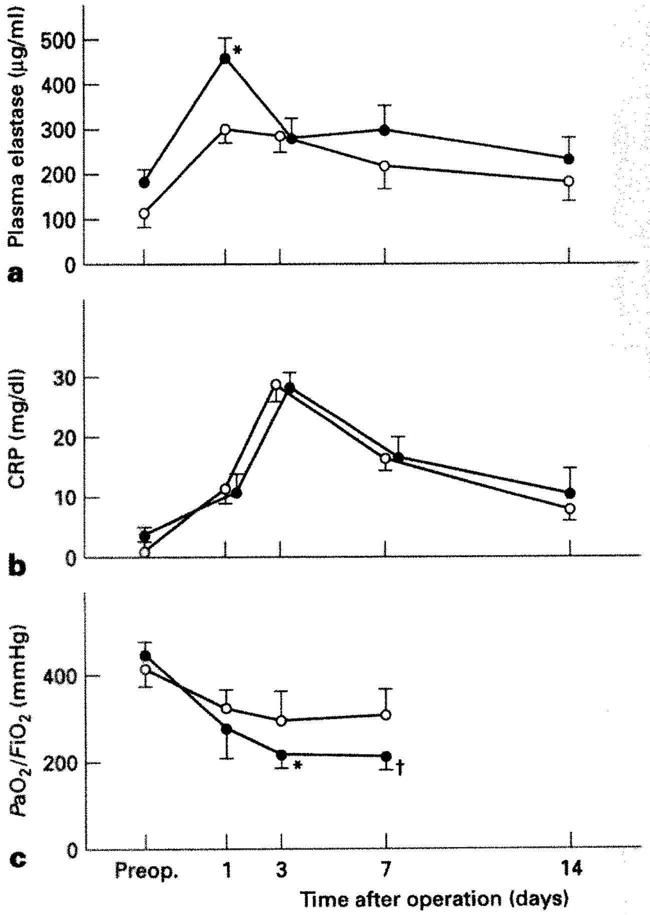

Fig. 4 Kinetics of a plasma elastase b serum C-reactive protein (CRP) and c ratio of arterial partial pressure of oxygen (PaO_2) to fraction inspired oxygen (FiO_2) in group I (●) and group II (○). Values are mean(s.e.m.). $^*P<0{\cdot}05$, $^\dagger P<0{\cdot}01$ *versus* group II (Student's *t* test)

Postoperative pulmonary complications

There were two patients with acute lung injury and four with ARDS in group I while five had acute lung injury and six had ARDS in group II. All patients in group I had pulmonary impairment, compared with 11 of 13 patients in group II. Pneumonia was associated with ARDS or acute lung injury in five of 19 patients, all in group I ($P<0{\cdot}05$). All patients recovered with intensive care.

Discussion

This study has shown an association between TNF-α and IL-1β and pulmonary complications following oesophageal surgery. *In vitro* the TNF-α and IL-1β producing capacities of peripheral monocytes greatly increased the day after surgery (TNF-α 400 pg/ml or more and IL-1β 200 pg/ml or greater) in six of 19 patients studied. This group also had significantly higher levels of plasma elastase on the day after operation and significantly higher levels of serum IL-6 and lower levels of PaO_2/FiO_2 with bilateral lung infiltration (acute lung injury and ARDS) on days 3–7. Excessively high producing capacities of TNF-α and IL-1β of peripheral monocytes *in vitro* the day after oesophagectomy appeared to be associated with subsequent pulmonary impairment. Five of these patients developed postoperative pneumonia, following acute lung injury or ARDS compared with none of the remainder.

Patients with excessively high capacities of TNF-α and IL-1β in their monocytes measured the day after operation also had significantly higher levels of these cytokine producing capacities before operation (TNF-α 200 pg/ml or greater and IL-1β 100 pg/ml or more) compared with the remaining patients. The reason for the priming of these monocytes remains unknown.

TNF-α and IL-1β are responsible for the induction of IL-6[22,23] which has many functions including the ability to induce the production of acute-phase proteins, in particular CRP, by hepatocytes[24,25]. After major surgical injury, serum IL-6 increases rapidly followed by an increase in serum CRP level[26,27]. The increase in serum IL-6 level following surgery is closely correlated with the duration of operation and blood loss[23,28]. Thus, an increase in serum IL-6 level following surgery is considered to reflect the production of TNF-α and IL-1β by monocytes. This is supported by the present study which showed that changes in the TNF-α and IL-1β producing capacities of peripheral blood monocytes *in vitro* are correlated with those in the serum IL-6. *In vitro* TNF-α and IL-1β producing capacities of monocytes seem to reflect the real production of these cytokines by monocytes *in vivo*, triggered by surgical trauma.

Several risk factors are associated with pneumonia following transthoracic oesophagectomy, including advanced age[29], smoking[30], chronic obstructive pulmonary disease[31], malnutrition[32], host immune defence impairment[5] and pulmonary dysfunction[29]. The present study showed in addition that acute lung injury and ARDS, induced by the overproduction of inflammatory cytokines, can lead to pneumonia following oesophageal surgery.

Preoperative TNF-α and IL-1β producing capacities of monocytes were significantly higher in patients who developed postoperative pneumonia. No association was observed for serum IL-6, plasma elastase or serum CRP before surgery. Preoperative TNF-α and IL-1β producing capacities in peripheral blood monocytes might be useful for predicting pulmonary complications following oesophageal surgery.

Vascular Surgical Society of Great Britain and Ireland Abstracts

The following abstracts are from the papers presented at the 31st Annual Conference of the Vascular Surgical Society of Great Britain and Ireland, held in London, UK, on 26–28 November 1997. President of the Society, Professor Averil O. Mansfield, was in the Chair.

Abdominal aortic aneurysm repair: a 21-year experience

A. W. Bradbury, D. J. Adam, K. R. Makjdoomi, W. P. Stuart, J. A. Murie, A. McL. Jenkins and C. V. Ruckley, *Royal Infirmary, Edinburgh, UK*

Studies from other countries report that the operative mortality rate following abdominal aortic aneurysm (AAA) repair is declining, as is the proportion of patients operated as an emergency for symptoms and/or rupture. This may not be the situation in the UK. The results of infrarenal AAA repair in a single unit over 21 years (1976–1996) were reviewed by analysis of a prospectively gathered computerized database.

Some 492 patients (32·5 per cent) underwent elective repair of an asymptomatic AAA; 194 (12·8 per cent) elective repair of a symptomatic AAA; 156 (10·3 per cent) emergency repair of a symptomatic AAA; and 673 (44·4 per cent) repair of a ruptured AAA. There has been a tenfold increase in the number of repairs performed annually but no change in the proportion of patients in each group. The operative mortality rate was 6·1, 5·8, 14·1, and 37·0 per cent respectively and has increased in all four groups over the study. There has been a significant increase in age in those having elective surgery for asymptomatic AAA but not in the other groups.

This is the largest ever reported single-centre experience with infrarenal AAA repair. Disappointingly, it is still the minority who have elective surgery before the onset of symptoms and/or rupture. Despite surgical specialization, the operative mortality rate is increasing. This may be due to increasing patient age and comorbidity but is difficult to prove.

Survival after repair of ruptured aortic aneurysm: an anaesthetic view

P. J. Gibbs, S. G. Darke and S. D. Parvin, *Royal Bournemouth Hospital, Bournemouth, UK*

This study assessed the influence of a senior vascular anaesthetist on early survival following surgical repair of leaking abdominal aortic aneurysm (AAA).

The study was a retrospective audit of 150 consecutive ruptured AAAs repaired between January 1992 and November 1996. Outcomes were calculated, according to the three vascular and 23 non-vascular anaesthetists, at 10 and 30 days. Results are presented both for the group as a whole and for the 113 patients over 70 years of age.

One hundred and nineteen repairs were performed by one of the two consultant vascular surgeons and the remainder by senior trainees. The seniority of the surgeon did not influence outcome. In the over 70s the vascular anaesthetists achieved significantly better survival at 10 and 30 days. For the whole group this improved survival was only significant at 10 days.

Anaesthetist	No. of repairs	Mean age (years)	10-day survival	30-day survival
Over 70 years	113			
Vascular	54	77·0	39*	36*
Non-vascular	59	75·7	28	25
Whole group	150			
Vascular	69	74·6	49†	44
Non-vascular	81	73·0	45	41

$^*P<0{\cdot}01$, $^\dagger P<0{\cdot}05$ (χ^2 test)

It would appear that, as with surgery, there is a potential benefit for subspecialization in vascular anaesthesia.

Changing pattern of aortic aneurysm workload in a single centre following introduction of a programme of endoluminal repair

J. Brennan, R. Waugh, W. Yu, M. Stephen, G. White and J. May, *Royal Prince Alfred Hospital, Sydney, Australia*

A programme of endoluminal aneurysm repair was introduced in 1992 and its effect on workload was assessed by retrieving data for all patients undergoing surgical treatment of an infrarenal aortic aneurysm between February 1990 and January 1997. Operations were categorized as open, emergency, endoluminal (successful) and endoluminal (conversion).

Year	Open	Emergency	Endoluminal (successful)	Endoluminal (conversion)	Total
1990	62	10	—	—	72
1991	56	20	—	—	76
1992	44	22	0	5	71
1993	49	16	13	5	83
1994	62	17	40	4	123
1995	54	10	33	2	99
1996	48	10	43	2	103

There was a 48 per cent increase in workload from a mean of 73 operations in the first 3 years to 108 in the last 3 years, due predominantly to endoluminal cases. In 1996 open operations accounted for 47 per cent of the total and successful endoluminal procedures for 42 per cent, compared with 59 and 16 per cent respectively in 1993. The conversion rate fell from 100 per cent in the first year to 4 per cent in 1996.

The endoluminal programme has increased the number of aneurysms treated but has not altered significantly the number of open or emergency cases. With increased experience the endoluminal group now constitutes almost half of the elective workload at an acceptably low conversion rate.

Hidden hazards of blood transfusion during elective aortic aneurysm repair: a comparison of autologous and homologous products

S. P. Cavanagh, S. E. Estoale, S. M. Parkin, S. Noblett, M. J. Gough and S. Homer-Vanniasinkam, *General Infirmary, Leeds, UK*

Cell-savers are increasingly used during aortic aneurysm (AAA) repair allowing autologous transfusion of red cells in saline. However, the infusate may contain other constituents of whole blood and inadvertent transfusion of activated neutrophils (PMN) (increased CD11b, CD18 expression, decreased L-selectin expression), proinflammatory cytokines (interleukin (IL)-1, IL-6, IL-8, tumour necrosis factor (TNF)α) and lipid mediators (leukotriene B_4, LTB_4) could promote a systemic inflammatory response syndrome. Levels of these mediators have been measured in ten patients during AAA repair, in the infusate from a cell saver and in 10 units of homologous packed cells.

	Patient	Infusate	Packed cells
WBC ($\times 10^9$ per litre)	5·55 (4·60–7·10)	5·65 (4·70–6·15)*	7·20 (5·90–8·55)†
Neutrophils ($\times 10^9$ per litre)	4·40 (3·38–5·42)	4·25 (4·05–4·95)	2·30 (0·75–3·55)*†
Monocytes ($\times 10^9$ per litre)	0·14 (0·09–0·16)	0·14 (0·10–0·21)	0·80 (0·60–1·40)*†
Lymphocytes ($\times 10^9$ per litre)	1·20 (0·91–1·32)	0·90 (0·62–1·65)	4·90 (3·60–6·20)*†
CD11b	160 (132–256)	538 (353–1131)*	875 (689–938)*
CD18	117 (105–131)	194 (148–228)	199 (153–210)*†
L-selectin	60 (47–62)	52 (35–75)	232 (157–241)*†
LTB$_4$ (pg ml^{-1})	7 (4–11)	264 (129–480)*	56 (36–164)*†
IL-6 (pg ml^{-1})	20·15 (17·75–24·85)	39·05 (24·25–100)*	4·65 (4·60–5·00)*†
IL-8 (pg ml^{-1})	1·00 (0·25–3·00)	10·50 (5·10–27·05)*	14·00 (9·65–26·00)*

Values are median (interquartile range). Negligible levels of IL-1 and TNF-α were detected. WBC, white blood cells. *$P<0\cdot0001$ *versus* patient, †$P<0\cdot0001$ *versus* infusate

The results confirm that the cell-saver infusate contains activated PMN (CD11b, CD18, L-selectin), monocytes and lymphocytes, and increased levels of LTB$_4$, IL-6 and IL-8. Although the transfusion of these cellular and biochemical factors could be detrimental the biological significance of this potential insult requires further assessment. Since similar results were obtained from homologous packed cells (with greater numbers of cytokine producing monocytes and lymphocytes) the other clinical advantages of autologous blood transfusion favour continued use of cell-saver devices.

Transferring patients with ruptured abdominal aortic aneurysm to a regional vascular surgery unit does not prejudice outcome

D. J. Adam, I. V. Mohan, W. P. Stuart, A. W. Bradbury, J. A. Murie and A. McL. Jenkins, *Royal Infirmary, Edinburgh, UK*

It is not known whether having to transfer patients with ruptured abdominal aortic aneurysm (AAA) prejudices outcome. The aim of this study was to examine the relationship between transfer distance and outcome.

Transfer distance was defined as the road distance between this regional vascular unit and the patient's residence. Unit data were obtained from a prospectively gathered computerized database. Population data for this catchment area (population 1·2 million; area 4500 square miles) were obtained from the Information and Statistics Division (ISD) of the National Health Service.

Between 1 January 1989 and 31 December 1995, 972 patients with ruptured AAA were identified by the ISD. Of these 214 patients (23 per cent) were certified dead in the community, 551 (57 per cent) were certified dead in hospital and 202 (20 per cent) survived. Of 381 patients transferred to this unit, 316 operated patients travelled significantly further (median 6·9 (range less than 1 to 39) miles) than 65 non-operated patients (median 3·1 (range less than 1 to 36) miles) ($P=0\cdot0001$, Mann–Whitney U test). Of 316 operated patients, there was no significant difference in transfer distance between 188 (59 per cent) who survived (median 5·5 (range less than 1 to 31) miles) and 128 who died (median 5·5 (range less than 1 to 29) miles) ($P=0\cdot9$).

Only 39 per cent of patients known to have a ruptured AAA were transferred to this regional vascular unit. However, there was no significant difference between transfer distance and operative mortality rate in these patients. These data suggest that transferring patients with a ruptured AAA to a regional vascular unit does not appear to prejudice outcome.

Abdominal aortic aneurysm wall compliance and future risk of rupture: a preliminary analysis

K. Wilson, A. W. Bradbury, M. Whyman, P. Hoskins, P. McCollum, A. Lee, F. G. R. Fowkes and C. V. Ruckley, *Royal Infirmary, Edinburgh, UK*

Abdominal aortic aneurysm (AAA) compliance, as determined by the pressure-strain elastic modulus (Ep) and stiffness (β), may be related to size, growth and risk of rupture. The relationship between AAA compliance and clinical outcome was determined.

Compliance was measured using an echo-tracking device (Diamove, Teltec, Lund, Sweden). Patients with a non-operated asymptomatic AAA ($n=112$), recruited from five different centres, underwent a single baseline compliance measurement and were followed for a median of 7 (range 2–18) months.

Seven patients ruptured their aneurysm and 16 underwent operative repair for non-ruptured AAA (two because of the onset of symptoms; 14 because of an increase in size). Ruptured AAAs had a lower Ep and β (*Table*) but there was no correlation between compliance and aneurysm size.

	Rupture ($n=7$)	Operated non-rupture ($n=16$)	Not operated or ruptured ($n=112$)	P value*
Diameter (mm)	54·9 (46·9–72·0)	49·2 (42·4–70·3)	45·0 (28·8–77·2)	<0·01
Ep (N m^{-2})	2·16 (1·59–3·72)	2·45 (1·22–7·58)	2·79 (0·55–9·46)	<0·01
β	15·0 (9·1–23·0)	17·3 (9·9–51·5)	18·2 (4·0–71·6)	<0·01

Values are median (range). *Kruskal–Wallis non-parametric analysis of variance three column comparison of median values

Preliminary data from this multicentre, prospective study suggest that AAA compliance measurements may be able to provide a more precise estimate of rupture risk than size or growth rate alone.

Value of atherosclerotic plaque characterization in balloon angioplasty of lower limb arteries

S. Aly, K. Sommerville, P. D. Coleridge-Smith and C. R. Bishop, *The Middlesex Hospital, London, UK*

Balloon angioplasty plays an important role in current treatment of peripheral arterial disease and its major limitation is restenosis. The effect of plaque morphology on angioplasty outcome was assessed.

Thirty patients (20 men, ten women; mean age 63 (range 53–85) years) with peripheral arterial disease were treated by angioplasty. Patients were scanned by Acuson duplex imaging. Computer-assisted image analysis was used to determine the mean pixel value (MPV) of grey scale of plaque. Lesion echogenicity was classified into: grade 1, less than 50 MPV (soft lesion); grade 2, 50–150 MPV (mixed lesion); and grade 3, more than 150 MPV (fibrocalcified). Arteries were scanned and images analysed 24 h before angioplasty and 24 h and 3, 12, 36, 52 and 65 weeks after angioplasty.

Forty-two lesions were examined (18 iliac, 24 femoropopliteal). Of 18 iliac lesions, four were grade 1, 12 grade 2 and two grade 3. In 24 femoropopliteal lesions five were grade 1, 16 grade 2 and three grade 3. All grade 1 lesions reoccluded at 3–12 weeks while at 36 weeks 80 per cent of grade 2 lesions and 60 per cent of grade 3 lesions did not show restenosis ($P<0\cdot0001$). There was no association between restenosis and symptoms.

This study has shown that soft echolucent atherosclerotic plaque restenoses quicker than mixed or fibrocalcified plaque. Plaque characterization may be of value in predicting the outcome of angioplasty.

Effect of intraoperative leucodepletion on neutrophil count and activation and cytokine production following limb salvage surgery

S. P. Cavanagh, A. Rawstron, M. J. Gough and S. Homer-Vanniasinkam, *General Infirmary, Leeds, UK*

Neutrophils (PMNs) promote ischaemia–reperfusion injury and PMN depletion ameliorates the injury in animal models. In ten patients undergoing limb salvage surgery the effect of PMN depletion (double-lumen femoral venous catheter, extracorporeal circuit, leucocyte filter, flow rate 200 ml min^{-1} for 15 min) on PMN count, adhesion molecule expression (CD11b, CD18, L-selectin: PMN activation) and cytokine levels (interleukin (IL)-6, IL-8, tumour necrosis factor (TNF)α) has been assessed compared with those in ten controls, in peripheral (PER) and femoral (FEM) venous blood at baseline (T_0) and 4 h (T), 24 h (T_{24}), 3 days (T_{3D}) and 6 days (T_{6D})after reperfusion.

PMN counts in filtered blood fell from 4·04 (range 2·55–5·75) to 0·72 (range 0·42–1·30) × 10^9 per litre ($P = 0·002$) and 1·08 (range 0·10–1·89) × 10^9 per litre ($P = 0·012$) after 5 and 15 min of filtration. PMN adhesion molecule expression was always lower in patients undergoing filtration (FEM and PER; significant to T_0 FEM ($P < 0·0001$), T_4 PER ($P = 0·0195$), T_{24} FEM ($P = 0·0012$) and T_{3D} ($P = 0·0140$) for CD11b, in T_0 PER ($P < 0·0001$) and T_{24} FEM ($P = 0·0311$) for CD18, and in T_4 PER ($P = 0·0072$) for L-selectin). Similarly filtration reduced IL-6 levels (all FEM and PER; significant at T_0 FEM and T_0 PER ($P = 0·0001$), T_{3D} ($P = 0·0256$) whilst TNF-α levels were higher, particularly in T_0 PER and T_4 PER ($P = 0·0001$). Finally, IL-8 levels were lower in PER samples (T_0, T_{24}; $P = 0·0001$) but higher in FEM samples (T_4, T_{24}; $P = 0·0001$).

This study suggests that PMN depletion in humans results in cellular (PMN activation: decreased levels of CD11b, CD18) and biochemical (decreased IL-6 level: reduced PMN-dependent cytokine; increased IL-8 level: inhibits PMN adhesion, perhaps via decreased L-selectin; increased TNF-α: inhibits PMN release) changes that should ameliorate ischaemia–reperfusion injury. The technique appears safe and is worthy of further investigation.

Increased proteolytic activity in acute carotid plaques

I. M. Loftus, S. Goodall, M. Crowther, L. Jones, P. R. F. Bell, A. R. Naylor and M. M. Thompson, *Leicester Royal Infirmary, Leicester, UK*

It is now generally accepted that acute changes in the atherosclerotic plaque are a prelude to the onset of clinical syndromes including stroke and myocardial infarction. There remains uncertainty about what causes this sudden change from a stable to an unstable plaque. Proteolytic enzymes (matrix metalloproteinases (MMPs)) have been implicated in previous studies. The aim of this study was to establish the character, level and expression of MMPs in carotid plaques and to correlate proteolytic activity with clinical status, spontaneous cerebral embolization and plaque histology.

Carotid plaques were obtained from 75 consecutive patients undergoing endarterectomy. Patients were divided into four groups according to symptomatology (group 1, asymptomatic; group 2, transient ischaemic attack/stroke/amaurosis fugax over 6 months; group 3, symptoms between 1 and 6 months; group 4, symptomatic within 1 month). All patients underwent preoperative and intraoperative transcranial Doppler (TCD) monitoring. Carotid plaques were collected and subjected to histological examination and quantification of MMPs.

	Group 1 ($n = 20$)	Group 2 ($n = 16$)	Group 3 ($n = 18$)	Group 4 ($n = 21$)
MMP-9 (ng)	31·5*	30·5*	30·6*	125·7*
Patients with emboli (TCD)	2	1	7	13
Rupture on histology	2	1	5	8

Values are median. *$P = 0·003$ (Kruskall–Wallis test)

There was no significant difference between the groups in MMP-1, -2, or -3, nor in the serum levels of all subtypes. The MMP-9 concentration was significantly higher in plaques undergoing spontaneous embolization ($P = 0·019$). Reverse transcriptase–polymerase reaction and *in situ* hybridization demonstrated higher levels of RNA for MMP-9 in highly symptomatic plaques which was localized to macrophages.

The concentration, production and expression of MMP-9 is significantly higher in unstable plaques.

Relationship between clinical grade of venous disease and calf perforating vein physiology

W. P. Stuart, A. W. Bradbury, D. J. Adam, P. L. Allan and C. V. Ruckley, *Royal Infirmary, Edinburgh, UK*

Subfascial endoscopic perforator surgery has rekindled the controversy regarding the role of calf perforating veins in the pathogenesis of chronic venous insufficiency. The relationship between grade of venous disease and calf perforating vein physiology was determined.

The following groups were studied: grade 0, 50 limbs with no clinical or duplex evidence of venous disease; grade I, 95 limbs with varicose veins only; grade II, 58 limbs affected by lipodermatosclerosis but not ulcer; and grade III, 108 ulcerated limbs. Duplex imaging was used to determine the number, diameter and blood flow within calf perforating veins.

Incompetent perforating veins (IPV) which permitted bidirectional flow were significantly wider (median 4 (range 1–8) mm) than competent, unidirectional flow perforators (median 2 (range 1–6) mm) ($P < 0·01$, Mann–Whitney U test). The relationships between clinical grade and perforator characteristics are shown.

	Grade 0 ($n = 50$)	Grade I ($n = 95$)	Grade II ($n = 58$)	Grade III ($n = 108$)
No. of limbs with perforators*	44 (88)	90 (95)	57 (98)	106 (98)*
No. of limbs with IPV*	3 (6)	49 (52)	48 (83)	97 (90)†
Median (i.q.r.) no. of perforators per limb	1 (1–2)	2 (1–3)	2 (1–3)	2 (2–3)‡
Median (i.q.r.) no. of IPV per limb	0 (0–0)	1 (0–2)	1 (1–2)	2 (1–2)‡
Median (range) perforator diameter (mm)	2 (1–4)	3 (1–8)	4 (1–11)	4 (1–8)‡

Values in parentheses are percentages. i.q.r., interquartile range; *$P < 0·05$, †$P < 0·001$ (χ^2 test), ‡$P < 0·001$ (Kruskal–Wallis test)

Deteriorating clinical grade of venous disease is associated with an increasing number and diameter of medial calf perforating veins, particularly those permitting bidirectional flow.

Sympathetic nervous system in peripheral vascular disease: a response sensitive to local tissue ischaemia

K. Delis, A. F. Lennox, K. Otah, A. Lauro, A. O. Mansfield, A. N. Nicolaides and J. H. N. Wolfe, *St Mary's Hospital, Imperial College, London, UK*

Lower limb venous pressure increases on dependency, stimulating a local sympathetic axon reflex and precapillary vasoconstriction. The resulting decrease in arterial calf inflow, known as the venoarteriolar response (VAR), is impaired in severe limb ischaemia. The effect of (1) early symptomatic peripheral vascular disease (PVD) and (2) tissue reperfusion following successful revascularization on this orthostatic reflex was examined.

The following patients were studied: group 1, 25 normal subjects; group 2, 25 patients with stable intermittent claudication due to infrainguinal PVD; and group 3, 25 patients with severe femoropopliteal PVD who had successful infrainguinal revascularization. All patients with PVD underwent angiography or duplex imaging, and all groups performed a treadmill test. Median resting ankle : brachial pressure index was 0·60 in group 2; in group 3 it was 0·42 before and 0·97 after revascularization. Laser Doppler fluxmetry measured the foot skin blood flux in the horizontal (HBF) and sitting (SBF) positions, and the VAR was calculated as (HBF − SBF)/HBF × 100 per cent. The pressure that elicits the reflex (pVAR) was calculated by inflating a pressure cuff over the distal calf to 60 mmHg to obtain sitting flux and deflating at increments until the skin flux rose.

	VAR (percentage postural flux change)	pVAR (mmHg)
Group 1	59 (51–67)*	45 (42–52)†
Group 2	30 (23–35)‡	22 (20–32)‡
Group 3	64 (56–72)	40 (35–42)

Values are median (interquartile range). $^*P = 0{\cdot}09$ *versus* group 3, $^{\dagger}P = 0{\cdot}01$ *versus* group 3, $^{\ddagger}P < 0{\cdot}0001$ *versus* groups 1 and 3 (Mann–Whitney *U* test)

Patients with claudication had significant impairment of the orthostatic response compared with normal subjects. After successful revascularization, and in spite of the extensive disease, this response returned to normal. Reperfusion increases tissue flow and decreases ischaemia, but does not alter the severity of atherosclerosis. The impairment of the orthostatic response is a result of tissue ischaemia, not the underlying pathology.

Colonoscopy with biopsy after aortic surgery: a unique study of the incidence of colonic ischaemia

M. Welch, L. Gurnani, M. Baguneid, P. D. F. Dodd and M. G. Walker, *Manchester Royal Infirmary, Manchester, UK*

Colonic ischaemia is a well documented complication of abdominal aortic reconstruction. In this prospective study all patients had routine preoperative and postoperative colonoscopy and biopsy to determine the true incidence and implications.

Fifty-six patients undergoing elective infrarenal aortic surgery, 28 for aneurysm and 28 for occlusive disease, were studied before operation and 1 week after operation.

All patients had normal macroscopic and microscopic appearances on preoperative biopsies. A 30 per cent incidence of postoperative colonic ischaemia was identified by histology (16 of 53 patients), almost half (seven of 16) had normal macroscopic appearances. Two factors exhibited a statistically significant association with development of ischaemia: prolonged cross-clamp time (mean 45 *versus* 35 min; $P < 0{\cdot}05$, Mann–Whitney *U* test) and postoperative diarrhoea (88 *versus* 13 per cent, $P < 0{\cdot}005$, Fisher's exact test). Co-morbidity was much higher in patients with ischaemia (81 *versus* 13 per cent; $P < 0{\cdot}005$, Fisher's exact test). Overall morbidity was significantly greater in the aneurysm group (46 *versus* 21 per cent, $P < 0{\cdot}05$, Fisher's exact test).

Colonic ischaemia after aortic reconstruction is more common than previously reported and, although mild and transient in many cases, is still associated with significant morbidity. When suspected, colonoscopy with biopsy is recommended.

Influence of systemic factors and pre-existing venous intimal hyperplasia on the outcome of infrainguinal arterial reconstruction with vein

D. K. Beattie, M. Sian, R. M. Greenhalgh and A. H. Davies, *Charing Cross Hospital, Imperial College, London, UK*

The relevance of raised serum lipoprotein (a), fibrinogen and homocysteine levels and the presence of pre-existing venous intimal hyperplasia (IH) to development of vein graft stenosis (VGS) has been disputed. This study investigated the association between these plasma factors, IH and outcome.

Lipoprotein (a), fibrinogen and homocysteine were measured in each patient and a vein biopsy taken. Pre-existing IH was graded semiquantitatively (0, no IH; I, mild; II, moderate; III, severe). Patients underwent duplex graft surveillance following femorodistal bypass.

Sixty-three grafts in 56 patients were recruited. Forty-seven were available for follow-up (mean postoperative follow-up 15 (range 5–34) months). Patients with no pre-existing IH had significantly lower homocysteine levels than those with IH ($n = 50$, $P = 0{\cdot}036$, Mann–Whitney *U* test), but significantly higher lipoprotein (a) levels ($n = 50$, $P = 0{\cdot}012$, Mann–Whitney *U* test). Twenty-four of the 47 grafts developed a VGS. There was no association between VGS and age, sex, diabetes or level of reconstruction. Mean serum fibrinogen was higher, although not significantly, in those with VGS (4·16 *versus* 3·18 g l^{-1}; $n = 45$, $P = 0{\cdot}09$, Mann–Whitney *U* test). Grafts with grade II or III IH were significantly more likely to stenose than those with grade 0 or I ($n = 40$, $P < 0{\cdot}01$, χ^2 test). There was a highly significant association between patients with grade II/III IH and/or raised fibrinogen and VGS ($n = 38$, $P < 0{\cdot}005$, χ^2 test).

Plasma homocysteine levels correlate with the presence of pre-existing IH, which itself correlates with subsequent VGS. There is a marked relationship between the presence of raised plasma fibrinogen levels and pre-existing IH with the development of VGS. These investigations may allow early identification of grafts requiring intense surveillance.

Vein graft aneurysms: conclusive proof of a systemic process

I. M. Loftus, M. Crowther, S. Goodall, A. R. Naylor, P. R. F. Bell and M. M. Thompson, *Leicester Royal Infirmary, Leicester, UK*

Although aneurysms are localized dilatations of the arterial wall, the question remains whether they are a focus of a generalized systemic disease process. There is evidence that extracellular matrix degradation secondary to matrix metalloproteinase (MMP) production forms the basis for aneurysm development. This study compared the risk of spontaneous aneurysm formation in vein grafts performed for aneurysms or occlusive disease.

Infrainguinal vein grafts performed during 1990–1995 were entered into a prospective audit and graft surveillance programme. Aneurysmal change was defined as a focal increase in graft diameter of greater than 1·5 cm (excluding false aneurysms and dilatation following graft angioplasty).

During the study, 221 grafts were performed in 200 patients for occlusive disease, while 24 grafts were performed in 21 patients for popliteal aneurysms. Graft surveillance revealed spontaneous aneurysm formation in ten of 24 grafts (nine patients) for aneurysm disease, but only four of 221 grafts (four patients) for occlusive disease ($P < 0{\cdot}001$, χ^2 test). To determine possible aetiological agents responsible for these results, long saphenous vein was harvested from patients undergoing bypass surgery and subjected to histological and biochemical analysis. Quantitative analysis of MMPs has revealed a twofold increase in the levels of MMP-2 and MMP-9 in patients with popliteal aneurysms compared with levels in patients with occlusive disease.

This study provides evidence that aneurysmal disease is a systemic process, possibly related to primay overexpression of MMPs within vascular tissue.

Minimally invasive long saphenous vein harvest

S. M. Hill, G. F. Nash and D. M. Nott, *Chelsea and Westminster Hospital, Imperial College, London, UK*

One of the disadvantages of infrainguinal bypass grafting using the long saphenous vein is the morbidity associated with the long incision required. A new technique has been devised in an attempt to reduce this morbidity.

An incision was made over the distal portion of the artery to be grafted on to, and a segment of long saphenous vein isolated via this incision. An Ethicon R subcu-retractor was passed proximally and subcutaneously over the length of the vein traversing up to the saphenofemoral junction. All side branches were clipped with an endoscopic clip applicator and cut with laparoscopic scissors. A standard infrainguinal incision was made to expose the femoral artery, the vein divided was at the saphenofemoral junction. Over 4 months ten primary infrainguinal bypasses have been performed using an endoharvested vein; these have been compared with operations in a similar group of sex- and age-matched controls using the standard technique. Mean(s.d.) operating time was 213(102) min for endoharvest *versus* 145(68) min for conventional harvest. Total wound length was 16(9) cm and inpatient stay 5(3) days for the endoharvested group compared with 39(13) cm ($P < 0{\cdot}01$) and 10(12) days ($P < 0{\cdot}1$). Follow-up has been short (mean 12 weeks) but so far all grafts remain patent.

Endoscopic vein harvesting is a promising technique with operating time becoming shorter with practice. It has the advantages of reduced wound complications, better cosmesis and decreased inpatient stay.

Influence of interhospital transfer on survival of patients with ruptured abdominal aortic aneurysm

D. Higman, V. Datta, R. M. Greenhalgh and A. H. Davies, *Charing Cross Hospital, Imperial College, London, UK*

Ruptured abdominal aortic aneurysm (AAA) is associated with a high hospital mortality rate. Often the reason for transferring a patient with a leaking AAA is the lack of an intensive care bed. It has been the authors' recent policy to accept all patients referred for repair of a ruptured AAA irrespective of their point of referral and availability of an intensive care bed.

Over 18 months 36 consecutive patients undergoing surgery for ruptured AAA were analysed.

Only 12 of the patients were primary referrals and the remaining 24 were referred from other hospitals. There was no significant difference in systolic blood pressure or haemoglobin concentration in either group. Six patients died perioperatively. Of the 30 survivors, 21 were transferred straight to the intensive care unit at this hospital and nine were transferred to another hospital. Patients transferred to other intensive care units were returned back when they were extubated and fit for transfer. Four of the 12 local patients died compared with 11 of 24 patients referred from other hospitals (*P* not significant). Of those initially transferred to another hospital's intensive care unit after surgery, two of nine died. There were no deaths in transit.

This study of ruptured AAA demonstrated that reasonable results can be obtained following interhospital transfer. Patients can be transferred safely once the procedure has been performed.

Prevalence of cerebral infarcts in relation to severity of carotid disease in the asymptomatic carotid surgery trial

P. Robless, on behalf of the ACST collaborators

In the Asymptomatic Carotid Surgery Trial (ACST) over 1630 patients have been randomized to determine if carotid endarterectomy (CEA) prolongs stroke-free survival compared with best medical treatment alone. Carotid duplex scanning is used to determine degree of stenosis and plaque echolucency. This study aimed to assess the prevalence of cerebral infarcts in relation to severity of carotid disease.

Patients with preoperative computed tomography (CT) were included. Those with previous contralateral CEA were excluded. Patients were divided into those with (1) bilateral carotid stenoses greater than 80 per cent, and unilateral stenosis greater than 80 per cent and 80 per cent or less and (2) those with more than 25 per cent and less than 25 per cent plaque echolucency.

Eight hundred and fifteen patients satisfied the criteria for the study giving 1630 vessels under consideration. All had information on degree of carotid stenosis by duplex scanning and 703 patients had infarction on plaque echolucency available. The prevalence of unexpected CT infarction was 23 per cent. Patients with bilateral carotid stenoses greater than 80 per cent (42 of 366) had the highest incidence of cerebral CT infarction (38 *versus* 23 per cent, $P = 0{\cdot}03$) compared with patients with unilateral stenosis above 80 per cent (324 of 366). Unilateral stenoses greater than 80 per cent (408 of 1630) had a higher incidence of ipsilateral CT infarct (18 *versus* 12 per cent, $P = 0{\cdot}002$) than unilateral stenoses of 80 per cent or less (1222 of 1630). Mantel–Haenszel test for linear association was significant in these groups ($P = 0{\cdot}03$). Those with greater than 25 per cent echolucent plaque showed no significant difference in the incidence of ipsilateral cerebral infarction.

In the ACST, bilateral carotid stenoses greater than 80 per cent had the highest incidence of cerebral infarction. Unilateral carotid stenosis greater than 80 per cent was associated with a higher incidence of ipsilateral cerebral infarcts on CT than unilateral stenosis of 80 per cent or less.

Training in abdominal aortic aneurysm surgery

A. W. Bradbury, J. A. Murie, A. McL. Jenkins and C. V. Ruckley, *Royal Infirmary, Edinburgh, UK*

Reduction in juniors' working hours and 'Calmanization' of training mean operative experience must be gained more efficiently. The aim of this study was to examine training in abdominal aortic aneurysm (AAA) repair, a nationally agreed vascular 'indicator operation' as defined by the Royal College Confidential Enquiry into Surgical Training (1996).

The study was an analysis of a prospectively gathered, computerized database of 994 consecutive AAA repairs between 1987 and 1996.

Since 1991 consultants have trained juniors at a significantly higher proportion of elective cases ($P < 0{\cdot}03$, χ^2 test). There has also been an increase in the proportion of emergency cases at which the consultant was not scrubbed ($P < 0{\cdot}01$). The operative mortality rate did not change significantly during the study and was not significantly related to consultant role in theatre.

	1987–1991		1992–1996	
	Percentage of operations	Operative mortality rate (%)	Percentage of operations	Operative mortality rate (%)
Elective AAA repair				
Consultant operating	73	7	54	5016
Consultant assisting	20	7	32	11
Consultant not scrubbed	7	0	14	7
Emergency symptomatic AAA repair				
Consultant operating	69	9	50	16
Consultant assisting	19	11	24	11
Consultant not scrubbed	12	7	26	7
Ruptured AAA repair				
Consultant operating	73	36	56	34
Consultant assisting	16	27	20	25
Consultant not scrubbed	11	20	24	45

These data indicate that supervised trainees can perform an increasing proportion of elective and emergency AAA surgery without increasing the operative mortality rate. Towards the end of training, trainee surgeons can safely operate alone in selected cases. Such experience is appropriate and desirable in the months leading up to a consultant appointment.

Vascular radiological experience in vascular surgical trainees

A. W. Garnham and M. Whiteley, *John Radcliffe Hospital, Oxford, UK*

It is recommended that vascular surgical trainees should have experience in diagnostic angiography and interventional radiological procedures. There are no data available to indicate whether such experience is being obtained.

A postal questionnaire was sent to 76 specialist registrars (SpRs) who had declared a subspecialty interest in vascular surgery.

There were 54 replies (response rate 71 per cent) from SpRs in all 6 years of training. Twelve (22 per cent) wished to become pure vascular surgeons, 39 (72 per cent) vascular/general surgeons and two (4 per cent) wished to be vascular/transplant surgeons. One respondent was undecided. Forty-seven (87 per cent) felt a formal radiological training to be important and 48 (89 per cent) wished to have training in interventional radiological techniques themselves. Only 26 (48 per cent) had had any exposure to vascular radiological techniques, five through research (three on animals only and two solely in aortic stent grafts), three abroad (two by travelling fellowships and one by a European training) and three in other UK centres; only 15 had received any vascular radiological experience in their own hospital. In all but three cases the SpRs had arranged their own radiological training, mainly on an informal basis.

Vascular SpRs feel it important to have a training in vascular radiological techniques. Fewer than half of the respondents had received any such training and most had arranged it themselves. Formal vascular radiological training should become a requirement of all vascular surgery training schemes.

Cross-training in endovascular and vascular surgery

M. M. Thompson, K. Varty, P. R. F. Bell and G. Fishwick, *Leicester Royal Infirmary, Leicester, UK*

To complete level 3 subspecialty training, vascular specialist trainees require experience in endovascular techniques. Such training would be desirable, but integrated programmes have yet to be instituted widely. This study reports a first year of experience of a programme designed to offer conventional surgical experience to radiologists and to train junior vascular surgeons in endovascular techniques.

The module adopted in this centre was for vascular surgical trainees to attend two lists in the interventional radiology suite per week and for a consultant radiologist to participate in one operating session, when appropriate. Neither of the radiology sessions was accompanied by radiology trainees and competition for cases therefore did not arise.

In the first year of this programme the higher surgical trainees performed 15 diagnostic arteriograms, 62 percutaneous angioplasties (PTAs) and insertion of one caval filter. The location of the PTA sites was iliac artery in 24 per cent, femoropopliteal in 43 per cent, crural in 19 per cent and vein graft in 14 per cent. Some 79 per cent of the interventions were intraluminal with the remainder being subintimal; 40 per cent were for occlusions. Twenty-eight endovascular aneurysm repairs were undertaken as joint surgical/radiological procedures in the operating theatre. During the same interval the consultant radiologist performed 30 femoral anastomoses and eight long saphenous high ties.

This integrated module of vascular training provides one system that facilitates training of both vascular surgeons and radiologists. It is likely that closer cooperation between radiologists and surgeons will be necessary in future and cross-training programmes should be mandatory.

Carotid duplex ultrasonography: can a variance of duplex methodology alter patient management?

S. Byrd, on behalf of the Asymptomatic Carotid Surgery Trial (ACST) collaborators

Carotid duplex ultrasonography, used in clinical practice since the 1980s, has replaced angiography as the first-line investigation for carotid stenosis. The aim of the study was to assess duplex methodology in 26 vascular laboratories used by 36 British surgeons in the Asymptomatic Carotid Surgery Trial. Specific attention was focused on areas which could significantly alter results such as: Doppler insonation angle, diagnostic criteria for determining degrees of stenosis and reporting process.

Routine vascular laboratory practice was evaluated by questionnaire. Respondents also submitted a copy of their individual diagnostic criteria and reporting form.

Results showed that 29 per cent used a standardized angle of 60°. A variable angle of 30°–60° was used by 71 per cent of respondents. Any change of Doppler angle will alter velocities within a given stenosis. For the 26 laboratories, there were more than 18 different individual criteria used for determining the degree of carotid stenosis. Findings were then reported as diameter reduction by 58 per cent, area reduction by 21 per cent and 17 per cent used both. To understand whether this variance could affect patient management, a single stenotic lesion was assessed by an independent sonographer. Doppler angle was varied at 50°, 60° and 70°. Resulting velocities were applied to individual laboratory diagnostic criteria. A predetermined cut-off point of 70 per cent was assigned to recommending possible surgical intervention. At a Doppler angle of 50°, four laboratories would consider this lesion as appropriate for surgery. At 60°, 13 laboratories would recommend surgery. At 70°, all laboratories indicated surgery.

Variance in carotid duplex methodology can change findings such that a patient's management may be altered. Further standardization of vascular laboratories will resolve this problem.

Is it time for a randomized trial of local *versus* general anaesthesia for carotid endarterectomy?

M. J. Gough, T. A. J. Calvey, A. J. McCleary, A. Bodenham and A. I. D. Mayor, *General Infirmary, Leeds, UK*

Although carotid endarterectomy (CEA) performed under local anaesthesia (LA) allows optimum cerebral monitoring and maintains cerebral autoregulation it is suggested that hypertension and catecholamine release increase cardiac morbidity. A recent meta-analysis of non-randomized studies

(2070 LA, 3447 general anaesthesia (GA)) suggests that death (0·82 *versus* 1·16 per cent), stroke (1·98 *versus* 5·31 per cent) and myocardial infarction (MI) (0·6 *versus* 1·3 per cent) are less frequent in patients having LA.

In a prospective study 89 CEAs were performed under LA (superficial and deep cervical plexus block; 20 ml 0·5 per cent bupivacaine, 20 ml 1 per cent prilocaine) and 101 under GA (1 mg alfentanil, 0·5–2·0 per cent isoflurane, nitrous oxide/oxygen). Although non-randomized, patients had a free choice of the type of anaesthetic. The sex ratio (LA M:F 65:24; GA 57:44), mean age (67·9 *versus* 68·1 years) and history of ischaemic heart disease (31 *versus* 34 per cent), hypertension (66 *versus* 56 per cent), smoking (52 *versus* 64 per cent) and diabetes (11 *versus* 14 per cent) confirmed that the two groups were similar, as did the indications for surgery (LA *versus* GA: transient ischaemic attack 38 *versus* 38 per cent; cerebrovascular accident 33 *versus* 32 per cent; amaurosis 23 *versus* 25 per cent; asymptomatic 6 *versus* 5 per cent; presence of greater than 70 per cent bilateral stenoses 37 *versus* 35 per cent).

	Local anaesthesia ($n = 89$)	General anaesthesia ($n = 101$)
Shunted	15 (17)	67 (67)
Stump pressure <50 mmHg	46 (52)	67 (67)
30-day stroke rate	0 (0)	4 (4)*
Perioperative MI	1 (1)	3 (3)
Death	1 (1)	2 (2)

Values in parentheses are percentages. *$P = 0{\cdot}057$ *versus* LA; $P = 0{\cdot}046$ *versus* LA for combined stroke/MI

These results support the concept that all complications of CEA may be less frequent when surgery is performed under LA, and reinforce the need for a prospective, randomized trial.

Identification of the unstable carotid plaque

T. J. Tegos, A. N. Nicolaides, T. S. El-Atrozy, S. Dhanjilm, M. Sabetai and D. Thomas, *St Mary's Hospital, Imperial College, London, UK*

The aim of this study was to determine the relationship between ultrasonographically evaluated carotid plaque echolucency, the degree of carotid stenosis on duplex imaging, the incidence of ipsilateral cerebral infarction on computed tomography (CT) and cerebrovascular symptoms.

One hundred and ten consecutive patients referred for the evaluation of carotid stenosis with 149 plaques, 59 symptomatic and 90 asymptomatic, having 50–90 per cent carotid stenosis were studied. Ultrasonographic images of the plaques were standardized by computer so that the grey scale median (GSM) of blood was 0–5 and of adventitia 180–200 on a linear scale 0–255 (interobserver variability, $r = 0{\cdot}93$). The GSM of the plaque was used as a measure of plaque echolucency. The stenosis was evaluated by duplex imaging, and the presence or absence of ipsilateral cerebrovascular symptomatology and CT infarction was noted.

GSM less than 45 and stenosis less than 70 per cent identified a group with a 34 per cent incidence of symptomatic plaques and 39 per cent incidence of plaques associated with ipsilateral cerebral CT infarction. GSM less than 45 and stenosis more than 70 per cent identified a group with incidences of 62 and 52 per cent respectively (high-risk group). GDM more than 45 and stenosis more than 70 per cent identified a group with corresponding incidences of 20 and 25 per cent, and GSM more than 45 and stenosis less than 70 per cent identified a group with incidences of 4 and 17 per cent respectively ($P < 0{\cdot}05$, χ^2 test).

These results indicate that computer-based plaque characterization and degree of stenosis can identify plaques at high risk of cerebral infarction and symptoms; aspects which have potential application in the management and natural history studies of carotid plaques.

S-nitrosoglutathione, a targeted nitric oxide donor, reduces embolization following carotid endarterectomy

J. Malloy, P. Baskerville, S. Fraser, J. Martin and H. Marcus, *King's College School of Medicine, London, UK*

Cerebral embolism is the major cause of stroke, but current antiplatelet and antithrombotic medications are suboptimal. Assessment of new agents is limited by a lack of *in vivo* models in which to evaluate their action. Carotid endarterectomy (CEA) creates a thrombogenic surface by endothelial denudation. The authors have previously demonstrated frequent embolic signals in the ipsilateral middle cerebral artery (MCA) of patients following this procedure using transcranial Doppler ultrasonography, despite aspirin therapy. An *in vivo* model of cerebral embolization has been developed in which the action of S-nitrosoglutathione (GSNO), a targeted nitric oxide donor, has been tested.

Twenty-four patients (12 control, 12 GSNO) were recruited before CEA. All were pretreated with aspirin 300 mg daily for at least 1 week before surgery. Transcranial Doppler ultrasonographic recording from the ipsilateral MCA was performed for 3 h after operation. The GSNO group received intravenous treatment of 4·4 nmol kg^{-1} min^{-1}, commenced at induction of anaesthesia and continued for 2 hours from skin closure. All data were recorded to digital audio tape for later blinded analysis offline.

There was a significant reduction in the number of embolic signals detected during the 3-h period in the GSNO group: controls mean(s.d.) 59·58(61·54) (median 38·5); GSNO 12·42(16·63) (median 7·5) ($P = 0{\cdot}0078$, Mann–Whitney U test).

Significant platelet aggregation and embolization occurred despite aspirin therapy. The targeted nitric oxide donor, GSNO, reduced embolization rates. This model allows the efficacy of new antiplatelet and antithrombotic agents to be determined using small patient numbers.

Macrophage infiltration within the cap of carotid plaques predicts the onset of cerebral ischaemic symptoms

T. Husain, C. R. Abbott, D. J. A. Scott and M. J. Gough, *General Infirmary, Leeds, UK*

Numerous studies have attempted to correlate clinical history with carotid plaque morphology but the mechanisms by which intraplaque factors precipitate the development of symptoms is largely undetermined. In coronary and aortic atherosclerotic lesions, macrophage infiltration of plaques, particularly within the cap and shoulder regions (SH), is associated with plaque instability.

Twenty-nine carotid endarterectomy specimens have been assessed using haematoxylin and eosin, Van Gieson and immunostaining with antimacrophage (HAM56) monoclonal antibody. Computerized planimetry was used to quantify the percentage area occupied by macrophages in the cap, SH and the entire sclerotic component (SC) of the plaques. These results were then correlated with the interval between the patient's last ipsilateral carotid territory symptoms and surgery.

Mean(s.e.m.) macrophage concentrations in the SC, SH and cap were 0·9(0·40), 1·57(0·31) and 2·52(0·46) per cent respectively (SC *versus* SH $P = 0{\cdot}03$; SC *versus* cap $P = 0{\cdot}002$; SH *versus* cap $P = 0{\cdot}0173$). While no relationship existed between the macrophage concentrations of the SC and the SH and the history of cerebral ischaemic events, there was a significant negative correlation between cap macrophage concentration and the time since the patient's last ipsilateral ischaemic symptom ($P = 0{\cdot}0177$).

Macrophage infiltration of plaques, particularly in the cap, may promote plaque instability and could be important in the pathogenesis of symptomatic cerebral ischaemia.

Is carotid endarterectomy a safe operation in the elderly?

R. M. Pemberton, A. Reid, N. J. M. London, P. R. F. Bell and A. R. Naylor, *Leicester Royal Infirmary, Leicester, UK*

While the incidence of thromboembolic stroke increases with age, general practitioners are less likely to refer patients aged over 70 years for carotid endarterectomy (CEA) because of a perceived higher operative risk. To determine the validity of this assumption a prospective audit of the risk of death and/or stroke in elderly patients undergoing CEA was undertaken.

Two hundred and thirty-five consecutive CEAs were performed in patients aged 70 years or more (median age 75 (range 70–88) years) between January 1992 and July 1997. All had an ipsilateral stenosis of greater than 70 per cent, and one-third had contralateral occlusion or severe stenosis. Exclusion criteria for operation were a concurrent illness giving an anticipated survival of less than 2 years, dementia or an inability to maintain independent living. Endarterectomy was performed under normotensive normocarbic general anaesthesia with systemic heparinization, routine patching and shunting, and monitoring by transcranial Doppler and angioscopy. During this time 317 CEAs were performed in patients aged less than 70 years.

Patient age	No. of CEAs	Death/ disabling stroke	Death/ any stroke
40–69 years	317	9 (2·8)	14 (4·4)
70–90 years	235	6 (2·6)	9 (3·8)

Values in parenthesis are percentages

The commonest single cause of morbidity was postoperative thrombosis (six of nine patients).

These findings suggest that CEA can safely be performed in selected patients and that age alone should not exclude consideration for surgery.

Management and outcome of 50 carotid sheath tumours

N. W. Cheshire and A. O. Mansfield, *St Mary's Hospital, Imperial College, London, UK*

Between 1985 and 1997, 50 carotid sheath tumours in 45 patients were managed. Forty-five surgical excisions were undertaken in 39 patients of whom four had bilateral tumours. Median age at presentation was 43 (range 20–79) years and tumours were almost twice as frequent in women (female to male ratio 1·9:1). Previous exploration had been performed on 20 tumours.

Preoperative nerve deficits were present in five patients (three involving X and XII nerves, one IX, X and XII nerves, and one Horner's syndrome). Thirty-five tumours arose from the carotid body, seven from the vagus nerve, one was a glomus jugulare tumour and two were sympathetic schwannomas. Of the carotid body tumours, two had metastases and 34 were completely excised; 19 required external or internal carotid artery excision. Ten tumours were adherent to cranial nerves, resulting in four permanent XII nerve palsies. Of the patients with vagal tumours, one had neuroendocrine secretion. Two of these seven patients required excision of an involved XII nerve. Both schwannomas and the jugulare tumour were successfully excised. There was one death from a subarachnoid haemorrhage. At mean follow-up of 5·9 years, two tumours have recurred and required re-excision.

These data demonstrate that surgical excision of tumours within the carotid sheath can be undertaken with acceptable morbidity and mortality rates, and a low incidence of recurrence.

Early discharge after carotid endarterectomy reduces cost without increasing complications

A. J. P. Sandison, M. Brooks, C. H. Wood and P. R. Taylor, *Guy's Hospital, London, UK*

Reducing the cost of carotid endarterectomy (CEA) is important, but must not cause an increase in complications. A prospective audit of investigations, results, hospital care and surgical outcome was undertaken over 5 years to evaluate the procedure. A patient survey on early discharge was also performed.

Median length of stay has reduced from 7 to 2 days including one night before operation, saving £750 per procedure. Overnight observation in the intensive care unit was replaced in 1993 by 4 hours of observation in the recovery suite, saving £1500 per procedure. Since 1995, angiography was only used when duplex findings were unclear, saving £240 per procedure. Cerebral computed tomography has been restricted to patients presenting with stroke. Complication rates have not altered despite these changes. One patient was readmitted within 30 days. Over 80 per cent of patients were pleased with early discharge.

Year	Median stay (days)	Cost saving per CEA (£)	Stroke and death rate (%)	Total neurological events (%)	Other compli- cations	Re- admission within 30 days
1992	7	0	0 of 24 (0)	0 of 24 (0)	2	0
1993	5	1800	3 of 34 (9)*	3 of 34 (9)*	2	0
1994	3	2100	0 of 35 (0)*	0 of 35 (0)*	2	0
1995	2	2490	3 of 51 (6)*	4 of 51 (8)*	1	0
1996	2	2550	2 of 67 (3)*	2 of 67 (3)*	3	1
Total			8 of 211 (3·8)	9 of 211 (4·3)	10	1

Values in parenthesis are percentages. *P not significant *versus* 1992 (Fisher's exact test)

Discharge from hospital the day after CEA is possible in over 90 per cent of patients without an increase in early readmission or complications, and is a safe way of increasing the cost effectiveness of CEA.

Maintaining vascular services and staying out of the red

R. F. M. Wood, J. D. Beard, J. A. Michaels, P. A. Gaines and A. E. Watson, *Northern General Hospital, Sheffield, UK*

In most Trusts, vascular activity forms part of the general surgical contract. The 'average specialty cost' of a surgical episode in this hospital is £880, considerably less than the real cost of treating a patient with arterial disease. Savings on minor surgery may compensate for this discrepancy as far as the contract with the local health authority is concerned. However, centres undertaking specialized tertiary referrals from surrounding health authorities under block contracts may find that this work constitutes a major 'loss leader'.

This vascular unit, which provides a tertiary service for a population approaching two million, had a shortfall on income for direct costs in 1995–1996 of £88,000. Surrounding purchasers were only prepared to negotiate on the basis of real additional costs incurred. The 'bottom up' costs of each case referred in during 1995–1996 were therefore calculated, including the cost of items such as minutes in theatre, radiology disposables, drugs, staff costs, length of stay, etc. This allowed accurate pricing of major vascular surgery such as ruptured aneurysm (£8702) and major emergency reconstructive surgery (£3436). On the basis of these costings an additional £100,000 of funding was secured from surrounding health authorities in the 1996–1997 contracting round. This has enabled the unit to cope with its previous overspend and has helped fund an additional consultant post.

Outpatient management of deep vein thrombosis

M. H. Thomas, V. O'Neill, C. Tovey, M. Creagh and D. F. O'Shaughnessy, *St Peter's Hospital, Chertsey, UK*

Patients with deep vein thrombosis (DVT) conventionally receive inpatient treatment with up to a week of intravenous heparin and conversion to warfarin. This study assessed the efficacy and safety of treatment with subcutaneous low molecular weight heparin (tinzaparin) administered once a day to outpatients.

During 1995, 632 patients attended the accident and emergency department with a possible diagnosis of DVT. They were initially screened using light reflection rheography (LRR), a previously validated technique, and those suspected of DVT then proceeded to venography and in some cases duplex imaging as well. Some 427 patients were LRR negative. Of the 205 who proceeded to venography, 110 had a venogram that was negative for DVT and 95 had a positive venogram. Ninety-one patients were treated according to the protocol, 11 had malignant disease, four had thrombophilia and the rest (84 per cent) were idiopathic cases.

Patients were weighed and given appropriate doses of tinzaparin and warfarin, then discharged home with a prepackaged treatment kit containing syringes, tinzaparin, warfarin and an instruction sheet. A district nurse visited to perform the subsequent five daily injections. Patients attended the next anticoagulation clinic, held twice weekly, to have their warfarin dose monitored. There were no thrombotic or embolic complications in any patient. No bleeding occurred during the 5 days on tinzaparin although there were two episodes of minor bleeding on warfarin. Over 725 hospital bed days were released by the use of this regimen.

The outpatient management of DVT is effective and safe.

Relationship between sex, symptoms and signs of venous disease and the results of colour flow duplex scanning: a population-based study

A. W. Bradbury, C. J. Evans, A. J. Lee, C. V. Ruckley and F. G. R. Fowkes, *Royal Infirmary, Edinburgh, UK*

The relationship between sex, venous symptoms and signs, and duplex findings in the general population was defined. Some 1566 subjects (699 men, 867 women) aged between 18 and 64 years, randomly selected from the registers of 12 family practices, underwent an interview, clinical examination and colour flow duplex scanning of both legs.

Women were more likely to have a history of varicose veins (13 *versus* 7 per cent, $P<0{\cdot}01$, χ^2 test), phlebitis (4 *versus* 1 per cent, $P<0{\cdot}01$) but not leg ulcer (0 *versus* 1 per cent, $P<0{\cdot}01$); and to complain of leg heaviness/tiredness (26 *versus* 14 per cent, $P<0{\cdot}01$), swelling (20 *versus* 7 per cent, $P<0{\cdot}01$), ache (49 *versus* 28 per cent, $P<0{\cdot}01$) and cramps (38 *versus* 31 per cent, $P<0{\cdot}01$). However, on examination, women were less likely to have superficial varices (23 *versus* 32 per cent, $P<0{\cdot}01$), skin changes of chronic venous insufficiency (CVI) (5 *versus* 9 per cent, $P<0{\cdot}01$), or reflux exceeding 0·5 s in the femoral (4 *versus* 9 per cent, $P<0{\cdot}01$) and popliteal (8 *versus* 14 per cent, $P<0{\cdot}01$) veins. There was no difference with respect to superficial reflux. There was a weak association between symptoms, superficial varices and superficial (but not deep) venous reflux on duplex in women ($P=0{\cdot}05$). In men there was a significant association between symptoms and skin changes of CVI ($P<0{\cdot}01$), but not between symptoms and reflux on duplex imaging.

Although 'venous' symptoms are significantly more common in women, men have a higher prevalence of superficial and deep venous disease on clinical and duplex examination. There is an inconsistent correlation between 'venous' symptoms, examination and duplex findings, particularly in women.

Prevention of leg ulcer recurrence: a role for the vascular surgeon?

A. S. K. Ghauri, J. G. Sullivan, M. R. Whyman, J. R. Farndon and K. R. Poskitt, *Cheltenham General Hospital, Cheltenham, UK*

Prevention of recurrent venous leg ulceration is a difficult and underestimated management problem. The aim of this study was to assess the influence of a vascular-led community ulcer service and venous surgery on long-term recurrence rates.

Vascular-led community clinics were introduced in 1995 with a one-stop assessment including ankle:brachial pressure index and venous duplex imaging. Patients were treated with compression bandaging and venous surgery was advised if superficial venous disease alone was detected. All healed patients received compression hosiery and were reviewed every 3 months. Recurrence at 6 and 12 months in all healed ulcers was recorded in 1994 and again in 1996 after introduction of the vascular-led clinics.

Vascular-led ulcer clinics reduced 6-month recurrence rates from 42 to 13 per cent and 1-year recurrence rates from 48 to 15 per cent ($P<0{\cdot}01$). Venous surgery further reduced 1-year recurrence from 20 to 5 per cent ($P<0{\cdot}05$). Ulcer recurrence was higher in the first 6 months compared with the second 6 months after healing ($P<0{\cdot}01$).

	Before ulcer clinics (1994)	Ulcer clinics (1996)	Ulcerated limbs (no venous surgery)	Ulcerated limbs (with venous surgery)
Limbs	113	119	80	39
6-month recurrence rate	47 (42)	15 (13)*	13 (16)	2 (5)
1-year recurrence rate	54 (48)	18 (15)*	16 (20)	2 (5)†

Values in parentheses are percentages. *$P<0{\cdot}01$ *versus* before ulcer clinics (χ^2 test); †$P<0{\cdot}05$ *versus* no surgery (Fisher's exact test)

A vascular-led ulcer service reduced venous ulcer recurrence. Lowest recurrence rates were seen in ulcerated limbs following venous surgery to superficial reflux. Colour venous duplex scanning is therefore essential in venous ulcer assessment.

Outcome of surgery for short saphenous vein reflux

S. Dimitri, P. R. Edwards, S. Kenny and L. de Cossart, *Countess of Chester Hospital, Chester, UK*

Short saphenous vein (SSV) surgery is more complex than that for the long saphenous vein (LSV). There is little in the literature to indicate the specific risks of the operation. A review of the outcome of SSV surgery from data collected prospectively in a single hospital is presented (1989–1996). Data were extracted from pro formas in the notes and a computerized database.

One hundred and twenty operations were performed (10 per cent of all superficial venous surgery). All surgery was performed by experienced surgeons. The vascular surgeons now undertake all SSV surgery. All patients underwent continuous wave Doppler (CWD) as outpatients; inexperienced surgeons tended to miss popliteal fossa reflux more often. Venous duplex imaging is now the norm before surgery but has increased over the years (1989–1991, none; 1992, six of 16; 1993, three of seven; 1994, 25 of 29; 1995, 39 of 44; 1996, 18 of 18).

Total morbidity was 17 per cent and the mortality rate was 2 per cent. Complications included paraesthesia (10 per cent), residual veins (4 per cent), wound infection (4 per cent), swelling (4 per cent) and deep vein thrombosis (2 per cent). There were two deaths, one from a pulmonary embolism in a patient undergoing combined LSV and SSV surgery and one from a ruptured liver in a patient on anticoagulants.

An unexpectedly high level of morbidity has been demonstrated. Patients should be aware of the risks especially in combined procedures. Duplex imaging helps to ensure that the correct procedure is undertaken, as an inexperienced operator with CWD examination may miss SSV reflux.

Systematic review of the randomized controlled trials of exercise therapy for intermittent claudication

G. C. Leng, on behalf of the Cochrane Peripheral Vascular Diseases Group, Oxford, UK

A systematic review was performed to determine whether exercise is an effective treatment for intermittent claudication. Two authors independently extracted details of trial quality on all randomized controlled trials of exercise *versus* control, or *versus* medical or surgical therapy in patients with intermittent claudication, and data on walking distance, measures of underlying disease and cardiovascular events. Meta-analysis was performed using the Peto method.

Nine trials were identified; five compared exercise with an untreated control group; two compared exercise with intervention (surgery and angioplasty); and two with drug regimens (antiplatelet therapy and pentoxifylline). Exercise therapy significantly improved maximal walking distance (odds ratio (OR) 6·51 (95 per cent confidence interval (c.i.) 4·36–8·66)), with an overall improvement in walking ability of 150 (range 74–230) per cent. Exercise significantly increased walking distance compared with angioplasty at 6 months (OR 2·17 (95 per cent c.i. 1·32–3·03)) and antiplatelet therapy (OR 1·06 (95 per cent c.i. 0·15–1·97)), but did not differ significantly from surgical treatment, and was less effective than pentoxifylline (OR −0·45 (95 per cent c.i. −0·66 to 0·24)). Exercise did not have a significant effect on the ankle:brachial pressure index (ABPI) or calf blood flow, and these outcomes were similar after angioplasty or antiplatelet therapy. Surgery significantly improved the ABPI (OR −0·27 (95 per cent c.i. −0·37 to −0·17)), but was associated with a higher rate of adverse events (18 per cent) and death.

Exercise is of significant benefit to patients with claudication, but further studies are required to determine the longer-term benefits of exercise compared with other successful treatments such as surgery and pentoxifylline, and to evaluate the cost effectiveness of different exercise regimens.

Total antioxidant capacity in patients with peripheral vascular disease is dependent on nutritional status rather than the severity of ischaemia

J. M. Robinson, I. Spark, S. Homer-Vanniasinkam, M. J. Gough, R. C. Kester and D. J. A. Scott, *General Infirmary, Leeds, UK*

Previous work indicates that a reduced total antioxidant capacity (TAC) increases the risk of postoperative infection in patients undergoing femorodistal bypass. It is not known whether such a reduction is dependent upon the severity of ischaemia or the patient's nutritional status. Thus the TAC and nutritional status of two groups of patients with differing severities of vascular disease was assessed (14 (nine men; median age 72 years) with critical limb ischaemia (rest pain, ankle pressure less than 50 mmHg) and 13 claudicants (seven men; median age 68 years)) and compared with that of ten controls (six men; median age 64 years). Nutritional status was assessed by mid-arm circumference, triceps skin fold thickness, body mass index, lean body mass, maximum voluntary contraction (hand grip dynamometer), bioelectrical impedance, and levels of serum albumin, prealbumin and transferrin.

Patients with peripheral vascular disease had a lower median TAC than controls (752 *versus* 1130 $\mu\text{mol l}^{-1}$, $P = 0{\cdot}05$, Mann–Whitney U test) although there was no difference between claudicants and patients with critical ischaemia (789 *versus* 721 $\mu\text{mol l}^{-1}$). However, TAC did correlate with maximum voluntary contraction ($r_s = 0{\cdot}64$, $P = 0{\cdot}037$), lean body mass ($r_s = 0{\cdot}60$, $P = 0{\cdot}043$) and serum transferrin level ($r_s = 0{\cdot}67$, $P = 0{\cdot}02$).

These results indicate that TAC is influenced by nutritional status rather than the severity of ischaemia.

Axial flow fields in a cuffed end-to-side anastomosis: effect of disease progression and angle in a simple *in vitro* model

L. D. Wijesinghe, S. W. Smye and D. J. A. Scott, *St James's University Hospital, Leeds, UK*

The addition of a distal vein cuff to a femorotibial polytetrafluoroethylene graft may improve patency but does not prevent the formation of intimal hyperplasia (IH). A flow vortex exists at the 'heel' of the cuff where shear stress is low and bloodborne factors which take part in thrombus formation or promote IH have an increased residence time. Little is known about the behaviour of this vortex with changing flow rate caused by disease progression.

A flow circuit driven by a pulsatile pump was connected to polished glass models of standard or cuffed (height 1 or 2 cm) end-to-side anastomoses (ESAs) (inflow diameter 6 mm; outflow diameters 2 mm, angles 15, 30, 45, 60°). The proximal outflow channel was occluded 2 cm from the heel. The motion of illuminated particles was captured on video and analysed frame by frame to measure the maximum vortex height. Flow rate was altered by a clamp on the inflow or outflow tubing simulating progression of disease.

	Flow rate (ml min^{-1})								
	80	100	120	80	100	120	80	100	120
	Standard ESA			1-cm cuff			2-cm cuff		
15°	44	41	42	77	77	79	121	119	122
30°	53	53	52	81	80	80	130	132	131
45°	68	66	69	95	96	96	150	148	151
60°	81	79	83	113	113	113	175	172	174

Values in the table are vortex height in pixels (median of five measurements). $P < 0{\cdot}05$ (15° *versus* 30°, 30° *versus* 45°, 45° *versus* 60°, Mann–Whitney U test)

Vortex height does not change with flow rate for a given cuff angle and ESA type, but increases with anastomotic angle ($P < 0{\cdot}05$, analysis of variance) and cuff height. The development of IH may be favoured by a tall cuff (large vortex) whereas a long and low cuff (shallow angle ESA, small vortex) may be able to better accommodate any IH before it causes a significant flow reduction. Although the smallest vortex is in a shallow standard ESA, the anastomosis volume may not be large enough to compensate for any IH that develops.

Prospective randomized trial of distal arteriovenous fistula as an adjunct to femoroinfrapopliteal bypass using polytetrafluoroethylene

A. Hamsho, D. M. Nott and P. L. Harris, *Royal Liverpool University Hospital, Liverpool, UK*

Formation of a distal arteriovenous fistula (AVF) has been advocated as an adjunct to prosthetic femoroinfrapopliteal bypass as a means of improving graft patency by augmenting blood flow above a thrombotic threshold velocity.

Over 6 years, 89 patients undergoing femoroinfrapopliteal bypass with polytetrafluoroethylene (PTFE) for critical ischaemia were randomly allocated to either AVF ($n = 48$) or control ($n = 41$). All patients had an interposition vein cuff fashioned at the distal anastomosis. Graft patency and limb salvage were assessed by means of life-table analysis.

Early trends in favour of AVF in the first 6 months were lost by 2 years. Graft patency with AVF after 6, 12, 18 and 24 months was 87, 55, 48 and 33 per cent respectively compared with 63, 43, 38 and 26 per cent for controls ($P > 0{\cdot}2$, log rank test). The limb salvage rate at 24 months in patients with an AVF was 59 per cent compared with 63 per cent in controls ($P > 0{\cdot}3$, log rank test).

The results of this prospective randomized controlled trial indicate that formation of a distal AVF confers no significant advantage in graft patency or limb salvage over interposition of a vein cuff in patients having a long, distal PTFE graft for critical ischaemia.

Infected infrainguinal grafts: the advent of methicillin-resistant *Staphylococcus aureus*

R. T. A. Chalmers, A. Mireskandari, G. Stansby, N. Cheshire, A. N. Nicolaides, A. O. Mansfield and J. H. N. Wolfe, *St Mary's Hospital, Imperial College, London, UK*

Infected infrainguinal bypass grafts pose a major threat to life and limb. Twenty-six patients with 27 infected infrainguinal grafts treated between January 1991 and July 1997 were studied retrospectively.

The study group comprised 18 men and eight women of median age 66 (range 44–88) years. There were 17 infected femoropopliteal (16 prosthetic, one vein) and ten infected femorodistal (nine prosthetic, one vein) grafts. The median time from graft placement to infection was 3 (range 1–36) months. Eighteen patients presented with groin symptoms (sinus, false aneurysm or bleeding). Six were treated initially with local therapy (debridement, closed irrigation). Five ultimately required complete graft excision. Of these, three had a further bypass placed with limb salvage whilst two required amputation. Of the 20 patients treated initially by complete graft excision, 15 eventually required major limb amputation. Between 1991 and 1995 the infecting organisms were *Pseudomonas* and methicillin-sensitive *Staphylococcus aureus*. However, of 14 cases treated in the past 3 years all have been due to methicillin-resistant *S. aureus* (MRSA). Four patients died during the same admission from advanced sepsis. In 1991, a total of 67 infrainguinal grafts were placed and two (3 per cent) became infected. The figure for the first 8 months of this year is six (11 per cent) of 55 grafts.

Infection involving an infrainguinal bypass graft is a disastrous complication with a high amputation rate, in spite of aggressive surgery to attempt limb salvage. MRSA infection has had serious consequences, particularly in patients with prosthetic grafts.

Shared emergency vascular cover between two district general hospitals: implications for a consultant service

K. Dawson, R. McFarland, A. Halliday and M. Thomas, *St Peter's and Epsom District General Hospital, Epsom, UK*

A rota for weekend emergency vascular cover between four consultants from two district general hospitals was commenced on 1 February 1997. The combined catchment area includes 550 000 people with an acceptable vascular workload including 71 operations for aortic aneurysm, 34 carotid endarterectomies and over 300 angiograms/angioplasties in the 12 months preceding this study. In the first 6 months of cross-cover all vascular emergency operations were performed by consultants with no intervals left uncovered. On 14 of 25 weekends there were no vascular emergencies requiring a consultant either to be phoned or to attend the hospital. The total workload for the other 11 weekends included ten vascular operations (ranging from one to five per consultant). Emergency aortic aneurysm repair was the most common procedure (five of ten). A consultant was required to attend one of the two hospitals on nine other occasions (average less than 1 h per visit). There were 13 phone calls (160 min total) during which consultants were asked for management advice on other cases.

The advantages of consultant cover for vascular emergencies are obvious. Reservations about travelling time, increases in emergency work or two-site cover were unfounded. The amount of emergency work generated per consultant was not excessive even when added to general surgical rota duties. Based on these results the rota is being extended to include another hospital with the addition of another consultant surgeon and the rota may be widened to include weekdays.

POSSUM and P-POSSUM: is there a difference?

L. D. Wijesinghe, T. Mahmood, D. J. A. Scott, D. C. Berridge, P. J. Kent and R. C. Kester, *St James's University Hospital, Leeds, UK*

Physiological and Operative Severity Score for enUmeration of Mortality and morbidity (POSSUM) has been proposed as a comparative audit tool which avoids the problems of case mix. However, it has been shown to overpredict deaths and an alternative system (P-POSSUM) was developed to overcome this problem. The methods of analysing POSSUM ('exponential') and P-POSSUM ('linear') predictions of death are different. The exponential method has not been well described and previous comparisons have therefore used the more straightforward linear analysis for POSSUM. The aim of this study was to compare the ratio of observed to expected deaths (O:E ratio) predicted by POSSUM and P-POSSUM using their correct methods of analysis in patients undergoing arterial surgery.

Some 312 consecutive patients (median age 72 (interquartile range 65–71) years; 68 per cent men) undergoing carotid endarterectomy (CEA; $n = 59$), aortic aneurysm repair (AAA; $n = 113$; 73 elective), femoropopliteal (FP; $n = 73$) or femorotibial (FT; $n = 67$) bypass, had their POSSUM and P-POSSUM scores calculated prospectively. The 30-day mortality rate was recorded using audit data, notes review and mortuary records. The O:E ratios were calculated using exponential analysis for POSSUM and linear analysis for P-POSSUM. To illustrate errors caused by using the inappropriate analysis, POSSUM and P-POSSUM were also analysed by linear and exponential analysis respectively.

There were 41 postoperative deaths (13 per cent), 25 in the AAA group (four elective); ten after FT; five after FP and one after CEA.

	POSSUM O:E ratio		P-POSSUM O:E ratio	
	Linear	Exponential	Linear	Exponential
All	0·59	0·91	1·08	0·62
CEA	0·66	1·05	0·95	0·71
AAA	0·61	1·02	0·99	0·72
FP	0·59	1·10	0·92	0·55
FT	0·70	1·00	1·01	0·68

Both POSSUM and P-POSSUM produce overall O:E ratios close to unity when the correct analysis is used. Incorrect use of linear analysis for POSSUM or exponential analysis for P-POSSUM makes each system appear to overpredict death.

Premature aortoiliac occlusive disease in young women is associated with thrombophilia

D. J. Adam, A. W. Bradbury, W. P. Stuart, J. A. Murie, A. McL. Jenkins and C. V. Ruckley, *Royal Infirmary, Edinburgh, UK*

It has been suggested that thrombophilia may be associated with the development of premature arterial occlusive disease. The aim of this study was to determine the prevalence of thrombophilia in young women with isolated aortoiliac occlusive disease (AIOD). Twenty-seven consecutive women aged under 50 years who presented with isolated AIOD and who underwent surgery or percutaneous angioplasty (with or without stent placement) were studied.

Patients had a thrombophilia screen comprising kaolin clotting time, diluted Russell viper venom time (DRVVT) with platelet neutralization, anticardiolipin immunoglobulin (Ig) G and IgM, antithrombin III activity, protein C activity, total and free protein S (immunological), activated protein C resistance activity and genetic test, and factor V (Leiden) genetic test.

One or more abnormality was detected in ten patients and comprised raised anticardiolipin IgG (five patients), raised anticardiolipin IgM (three), prolonged DRVVT not neutralized by platelets (three), prolonged kaolin clotting time (one), and low total and free protein S (one). One-third of patients with premature arterial disease in this study had detectable thrombophilia. All such patients should be screened for thrombophilia in order to identify treatable conditions.

Effect of renal artery stenting on renovascular renal failure

M. Pemberton, R. Preston, G. Stansby, C. Griffiths, W. Gedroyc, A. Al-Kutoubi, D. Taube and J. Wolfe, *St Mary's Hospital, Imperial College, London, UK*

Atherosclerotic renal artery stenosis is a common cause of progressive renal impairment. Percutaneous renal artery angioplasty (PTRA) may stabilize or improve renal function in 40–60 per cent of patients but may be followed by recurrence of the stenosis. It is not clear whether such patients should be considered for surgery or for stent insertion. The aim of this study was to determine the effect of insertion of a renal artery stent on the rate of progression of renal failure in patients with angiographically proven disease.

Of 428 PTRAs performed over 6 years, 20 stents were deployed in 18 patients (median age 69 (range 45–90) years) with renal impairment (median serum creatinine 252 (range 163–448) μmol l^{-1}) and haemodynamically significant native renal artery stenoses (more than 50 per cent). The indication for stent insertion was recurrent stenosis (nine of 20), ostial stenosis (eight of 20), immediate plaque recoil following PTRA (two of 20) and the presence of aneurysmal, in addition to stenotic, disease (one of 20). Stents were deployed successfully in 19 of 20 cases; one stent migrated beyond the stenosis during deployment. A false aneurysm requiring surgical intervention was the only complication. Median follow-up was 7 (range 1–34) months. In eight patients reassessed by arteriography, patency was confirmed at a median of 6 months. In 15 patients with serial serum creatinine measurement, improvement or stabilization in renal function occurred in nine.

Renal artery stent insertion has a high technical success rate and low morbidity and may benefit a significant number of patients in the short term. None the less prospective comparisons of stent deployment with surgery for renal artery stenoses are lacking.

Vascular access and the vascular surgeon: a survey of current practice

A. Bakran and D. Mitchell, *Royal Liverpool University Hospital, Liverpool and Southmead General Hospital, Bristol, UK*

Haemodialysis is used with increasing frequency in the elderly. The demand for vascular access surgery is met partly by vascular surgeons. The current practice and attitudes of members of the Vascular Surgical Society (VSS) towards this work has been surveyed.

Some 270 (67 per cent) of 400 members returned the questionnaire; of these 64 per cent worked in a district general hospital and 36 per cent in a teaching hospital; 67 per cent were general/vascular, 28 per cent vascular and 5 per cent vascular/transplant surgeons. Some 54 per cent of respondents provide access surgery, predominantly for renal failure. Only 6 per cent had a contractual obligation to provide such surgery and 7 per cent had an operating list specifically allocated to vascular access. Few surgeons have a heavy workload; over half performed fewer than 20 access cases per year, 20 per cent did 20–50 cases, 7 per cent 50–100 cases and 3 per cent more than 100 cases per annum.

Some 62 per cent of respondents had experienced vascular access during their training and 87 per cent felt that such surgery would be a valuable part of vascular training. Only 39 per cent of respondents' trainees are currently exposed to vascular access. Two-thirds of respondents felt that there was insufficient exposure to vascular access at British meetings with 54 per cent supporting increased exposure at the VSS.

A significant number of vascular surgeons are engaged in meeting the increasing demand for vascular access surgery. Training programmes in vascular surgery should include an adequate grounding in vascular access surgery.

Does the degree of peripheral vascular disease influence neutrophil function?

E. P. L. Turton, J. I. Spark, K. G. Mercer, D. C. Berridge, R. C. Kester and D. J. A. Scott, *St James's University Hospital, Leeds, UK*

Patients with peripheral vascular disease (PVD) have a threefold higher mortality rate compared with the general population, which is not fully explained by traditional risk factors. Leucocyte behaviour is altered in many different diseases and may be associated with an adverse clinical outcome. The aim of the study was to assess if increasing peripheral vascular ischaemia influenced neutrophil activation and degranulation.

Data were collected from 14 patients with mild/moderate claudication (ankle:brachial pressure index (ABPI) 0·8 (range 0·8–0·9)), 14 patients with severe claudication (ABPI 0·7 (range 0·6–0·8)), 25 patients with rest pain (ABPI 0·1 (range 0–0·2)) and 22 healthy age-matched controls (ABPI 1·2 (range 1·1–1·3)). Resting neutrophil count, neutrophil CD11b expression and plasma neutrophil elastase were measured. The urine albumin to creatinine ratio (UACR) was determined as a marker of systemic vascular permeability.

Patients with rest pain had significantly higher median CD11b expression ($P<0{\cdot}001$), plasma neutrophil elastase ($P<0{\cdot}05$), and urine albumin leak ($P<0{\cdot}01$) than patients with severe claudication, mild/moderate claudication and controls.

	Neutrophil CD11b (mean channel fluorescence)	Neutrophil elastase (mg l^{-1})	UACR (mg mmol^{-1})
Mild/ moderate	2·6 (2·0–3·0)	43·4 (35·3–66·3)	1·4 (0·7–2·7)†
Severe	3·5 (2·9–4·1)	44·6 (35·7–66·3)	2·3 (0·6–3·1)†
Rest pain	11·5 (7·3–15·2)*	80·3 (44·1–150·0)†	6·4 (1·0–7·5)*
Controls	2·2 (2·2–3·2)	57·4 (45·9–66·3)	0·5 (0·0–1·3)

*$P<0{\cdot}01$; †$P<0{\cdot}05$ *versus* control (Mann–Whitney U test)

This study provides evidence for the role of the neutrophil in PVD. Increasing tissue ischaemia is associated with increasing neutrophil activation and subsequent release of proteolytic enzymes with endothelial damage.

Clonality and restenosis: studies on human vascular smooth muscle cell cultures

P. Chan, R. Johnatty, K. Hopkinson, S. Fairburn, S. Nawaz and J. Zhang, *University of Sheffield and Imperial College at St Mary's, London, UK*

Restenosis after vascular intervention is largely due to vascular smooth muscle cell (VSMC) proliferation and matrix secretion. Previously, resistance to heparin-induced growth inhibition by VSMCs in culture has been linked to bypass graft restenosis *in* *vivo* in retrospective and prospective studies. Subpopulations of heparin-resistant and heparin-sensitive VSMCs probably occur in most individuals, leading to the hypothesis that the restenotic lesion may be a clonal growth of heparin-resistant cells.

VSMCs were cultured from 19 saphenous veins and six restenoses. Five to ten random subpopulations of cells from each specimen were separated in primary culture, cultured to passage two and analysed for heparin response. VSMCs were grown in 15 per cent serum with or without heparin 100 mg ml^{-1}; replenished twice weekly, and counted at 0, 7 and 14 days. Heparin inhibition was quantified as percentage inhibition comparing cell counts at day 14 in cultures with and without heparin. Some 215 (164 vein, 51 restenosis) cell subpopulations were analysed. Subpopulations derived from single samples of normal vein showed extensive variation with regard to heparin response (mean sample variation 596 per cent, corresponding to s.d. 22·6 per cent). Subpopulations derived from restenoses showed significantly less variation (mean sample variation 283 per cent, s.d. 18 per cent; $P = 0{\cdot}035$, analysis of variance, F-test). Restenosis cell subpopulations were confirmed to be more heparin resistant than normal vein cells (12·7 *versus* 37·3 per cent inhibition; $P = 0{\cdot}00002$, *t*-test). Random subpopulations derived from vein showed diversity; random subpopulations from restenosis showed relative uniformity.

These data support the concept that polyclonal subpopulations of VSMCs exist in normal veins, and that restenotic lesions represent an oligoclonal selection of heparin-resistant subpopulations.

Increased expression of metalloproteinase 2 in aneurysm-derived smooth muscle cells: the primary event in aneurysm formation?

M. M. Thompson, M. Crowther, L. Jones, R. D. Sayers and P. R. F. Bell, *Leicester Royal Infirmary, Leicester, UK*

Histopathological and biochemical studies of abdominal aortic aneurysms (AAAs) have demonstrated widespread elastin degradation, which has been attributed to increased levels of proteolytic metalloproteinases (MMPs) within the arterial tissue. Unfortunately, these historical studies have used established aneurysm tissue which makes primary aetiological changes impossible to differentiate from secondary degenerative effects. To overcome these problems, the present study has characterized the properties of isolated vascular smooth muscle cells (SMCs) cultured from the aortic wall of patients with either aneurysm or occlusive disease.

Sixteen individual SMC cell lines have been established from the aortic walls of aneurysm ($n = 9$) or atherosclerotic ($n = 7$) specimens. There was no difference in the proliferation rate between the two cellular groups. The production of MMP-2 and -9, in addition to that of their inhibitors TIMP-2 and TIMP-1, was quantified by direct assay (ng protein per 10^5 cells) and substrate gel enzymography (OD).

Cell line	MMP-2 (zymogram)	MMP-2 (ELISA)	MMP-9	TIMP-1	TIMP-2
AAA	2·6 (1·5–8·2)	361 (148–750)	1·2 (0·8–1·6)	677 (354–1014)	49 (29–90)
Athero-sclerotic	2·1 (1·6–6·4)*	324 (250–452)*	0·7 (0·6–0·8)	613 (363–3349)	8 (0–23)

Values are median (range). ELISA, enzyme-linked immunosorbent assay. *$P < 0{\cdot}05$ *versus* AAA (non-parametric analysis)

These results demonstrated an increased production of MMP-2 in aneurysm-derived SMCs. Quantification of patients' serum revealed no difference between the groups, neither did stimulation by interleukin 1β. However, analysis of MMP-2 gene expression by Northern blotting and reverse transcriptase–polymerase chain reaction demonstrated a primary overexpression of MMP-2 in aneurysm-derived cells.

The development of AAAs could be attributed to a single genetic locus. Data from this study suggest a primary enhancement of MMP-2 expression and production in aneurysm cells; MMP-2 may be a strong candidate gene for aneurysm development.

Vascular Surgical Society audit of acute lower limb ischaemia: outcomes of treatment and results of a validation exercise

W. B. Campbell, *on behalf of the Audit Committee of the Vascular Surgical Society of Great Britain and Ireland*

Initial figures from a 3-month audit of 539 cases of acute lower limb ischaemia have already been presented, and outcomes of treatment have now been analysed. At 30 days (or death/discharge) 70 per cent of limbs were definitely viable, 21 per cent after no vascular intervention, 59 per cent after anticoagulation only, 73 per cent after immediate embolectomy and 73 per cent overall after arteriography (74 per cent following subsequent thrombolysis and 81 per cent after bypass grafting). However, amputation rates (15 per cent overall) were similar for all types of treatment, ranging from 11 per cent after an arteriogram followed by embolectomy to 17 per cent after no vascular intervention (*P* not significant). Patients having no intervention were significantly older (median 83 years) than the cohort as a whole (median 73 years) ($P < 0{\cdot}001$). The overall mortality rate was 22 per cent.

These patients had been reported by 86 of 182 hospitals asked to participate, with substantial differences between regions (response rate 0–82 per cent). A validation exercise of 54 cases (10 per cent sample) from five non-participating hospitals showed no significant difference in age (median 73 *versus* 77 years in the 10 per cent sample), admitting specialty (55 *versus* 62 per cent vascular), or vascular advice (95 per cent in both). In each group 24 per cent had no intervention or anticoagulants, 21 *versus* 15 per cent embolectomy (*P* not significant), and 55 *versus* 43 per cent initial arteriograms (*P* not significant). At 30 days 64 per cent of limbs were viable and 20 per cent of patients had died in the validation sample (*P* not significant).

Small numbers of cases, diversity of treatments and selective use of different management strategies made direct comparisons between individual hospitals unrealistic. There was a variety of reasons for hospitals not contributing, but a 10 per cent validation sample showed no substantial differences from the original audit.

Criteria for arteriography following duplex evaluation of peripheral arterial disease

S. Aly, K. Sommerville, C. R. Bishop and P. D. Coleridge-Smith, *The Middlesex Hospital, London, UK*

Arterial reconstruction of the lower limb based on duplex imaging is controversial. This study assessed duplex accuracy and determined the conditions for which arteriography is mandatory following duplex imaging.

Some 156 patients (97 men, 54 women; mean age 68 years) were divided into two groups. Ninety patients (group 1) had duplex imaging and arteriography of the lower limb. Duplex accuracy was compared with arteriography (gold standard). Some 66 patients (group 2) had duplex imaging as the main investigation. Treatment was based on duplex findings. Arteriography was done on request of the surgeon. Duplex accuracy was also obtained for this group. The results of both groups were analysed and criteria for arteriography were obtained.

Some 3108 arterial segments (group 1) were examined in 177 limbs by both modalities; 466 arterial lesions were detected. Disagreement between duplex imaging and arteriography was found in 71 lesions. Duplex imaging had a sensitivity of 92 per cent, specificity 99 per cent, positive predictive value 91 per cent and negative predictive value 100 per cent with kappa of 0·87(0·06). Some 2310 arterial segments (group 2) were examined in 122 limbs by duplex imaging. Treatment decisions are shown in the *Table*. The criteria for arteriography following duplex were 1, failure of scanning to visualize an artery of interest; 2, failure of sonographer to comment on the profunda femoris, if considered important in clinical management; 3, difficult scanning of distal femoral and popliteal arteries; and 4, femorodistal bypass graft considered necessary.

Treatment	No. of patients	Percentage having arteriography
Discharge	8 (12)	0
Conservative	25 (38)	0
Balloon angioplasty	21 (32)	0
Surgery	3 (5)	67
Arteriography	9 (14)	100

Values in parentheses are percentages

Duplex imaging can be used safely for assessment of peripheral arterial disease and angioplasty can be planned without the need for diagnostic arteriography.

Variability of angiographic measurements of internal carotid artery stenosis between methods and observers

A. D. Fox, S. E. Robbins, M. S. Whiteley, P. Modi and J. Collin, *John Radcliffe Hospital, Oxford, UK*

Accurate measurement of carotid artery stenosis is an essential prerequisite for evidence-based carotid endarterectomy. Only the minority of patients in whom carotid duplex sonography is non-diagnostic now have carotid angiography. The aim of this study was to determine in this selected group the intraobserver and interobserver variability in the measurement of percentage stenosis.

Measurements were made in each case on the angiogram showing the greatest stenosis by 'eyeballing', calipers and a ruler, and jeweller's (Schindler scale) eyepiece graduated in fifths of a millimetre. Three independent observers were blinded to the measurements for each technique and to each other's results. One observer repeated all observations after 2 weeks to assess intraobserver error. Data were analysed using analysis of variance and the degree of correlation.

The three observers measured 90 stenoses by each of the three techniques. The correlation coefficients are tabulated.

Correlation	NASCET	ECST	Common carotid (CC) denominator
Intraobserver error			
Ruler	0·78	0·81	0·79
Scale	0·90	0·87	0·94
Intraobserver error 1			
Ruler	0·82	0·94	0·92
Scale	0·84	0·85	0·86
Eyeball	0·59	0·54	
Intraobserver error 2			
Ruler	0·82	0·44	0·80
Scale	0·80	0·84	0·87
Eyeball	0·74	0·73	

NASCET, North American Symptomatic Carotid Endarterectomy Trial; ECST, European Carotid Surgery Trial

The number of stenoses within each group measured by the ECST and CC denominator methods was similar, but NASCET classified 16 per cent more stenoses as mild (less than 30 per cent). NASCET also classified 50 per cent of severe stenoses according to ECST into the moderate group (30–69 per cent). There were poor correlations for interobserver and intraobserver measurements, and between methods of assigning category of stenosis.

The differences among observers and techniques for measuring angiographic carotid artery stenoses are considerable. These measurement discrepancies compound the known differences in percentage stenosis calculated by NASCET, ECST and CC denominator methods.

Fast gadolinium-enhanced magnetic resonance angiography: a technique to replace digital subtraction angiography?

J. M. Meaney, A. Mohamed, S. Homer-Vanniasinkam, M. J. Gough and I. Robertson, *General Infirmary, Leeds, UK*

Digital subtraction angiography (DSA) is an invasive procedure with small but finite risks (vascular trauma, contrast reaction, radiation). Magnetic resonance angiography (MRA) avoids these problems although standard time-of-flight imaging is slow and may not differentiate between tight stenoses and occlusions. A novel technique of MRA (gadolinium-enhanced contrast imaging; MRA-G) and a 'floating' table, as used for angiography, has been developed.

Twenty patients (ten with intermittent claudication, ten with critical ischaemia; 14 men and six women) underwent DSA and MRA-G. Gadolinium (40 ml, 0·1 mmol l^{-1}) was delivered via a peripheral vein over 2 min and imaging performed on a state of the art 1·5-T magnet. MRA images were acquired in 90 s over the abdomen/pelvis, thighs and legs (30 s each) providing images from the diaphragm to the foot. Reformatting allowed multiplanar views of all segments after a single contrast injection and scan.

All MRA-G studies were technically successful. Both the MRA-G and DSA films were assessed by two radiologists and two vascular surgeons. All occlusions/stenoses demonstrated by DSA were apparent on MRA-G. Furthermore patent crural vessels were detected by MRA-G in four patients when not evident on DSA. In all patients the therapeutic decision based on MRA-G was identical to that for DSA.

MRA-G may have a primary role for the rapid, non-invasive evaluation of patients with peripheral vascular disease providing images of comparable quality to DSA but with additional advantages of multiplanar views in all segments, routine demonstration of the whole of the intra-abdominal aorta and its branches, and enhanced imaging of crural vessels.

Percutaneous stent grafting of superficial femoral artery disease: 1-year follow-up of a pilot study

L. D. Wijesinghe, D. Kessel, L. Stock, I. Robertson, A. Nevelsteen and D. J. A. Scott, *St James's University Hospital, Leeds, UK*

Endovascular treatment has been proposed as an alternative to angioplasty or surgical bypass in patients with disabling claudication who have superficial femoral artery (SFA) occlusion. A pilot study was carried out to evaluate a balloon-mounted stent graft system made of polytetrafluoroethylene with proximal and distal anchoring stents.

After ethics committee approval, 20 patients with severe claudication (median age 64 (range 48–76) years; 19 men) were treated. All had SFA occlusions (median length 17 (interquartile range 10–20) cm) and satisfied the entry criteria (two or more run-off vessels; minimum SFA diameter at stent anchor sites 4 mm; proximal and distal disease-free anchor sites). Procedures were performed under local (seven patients), general (12) or epidural (two) anaesthesia using a 9-Fr introducer sheath, intravascular ultrasonography (IVUS) and image intensifier.

Vessel dissection by the introducer sheath accounted for two technical failures. Four other procedures were abandoned because IVUS measurements were outside protocol requirements. Of the 14 stents deployed, five occluded in the first month. Collapse of the unsupported section was the cause in two. The other three patients declined further intervention. Of the nine stent grafts patent at 1 year, only three are patent without intervention; one had angioplasty of an inflow stenosis and five developed significant intimal hyperplasia in the stented sections, requiring angioplasty with or without atherectomy. The 1-year primary, primary-assisted and secondary patency rates were 13, 24 and 36 per cent respectively (standard error 6, 10 and 11 per cent respectively). There were no deaths.

Preliminary results using this device are discouraging. If stent grafting of SFA disease is to become a viable alternative to surgery, fully supported designs which resist compression may be necessary, and the problems of intimal hyperplasia will have to be overcome.

Quality control during endovascular aneurysm repair

I. M. Loftus, M. M. Thompson, N. Lennard, S. Steele, J. Smith, G. Treharne, G. Fishwick and P. R. F. Bell, *Leicester Royal Infirmary, Leicester, UK*

With endovascular aneurysm repair there remains the potential for complications associated with graft deployment which would not occur during conventional surgery. If the technique is to achieve widespread acceptance it is essential to minimize such complications. The aim of this study was to employ direct measurement of aneurysm sac pressure and Doppler flow monitoring of the superficial femoral artery (SFA) to ensure complete exclusion of the aneurysm from the circulation.

An angiographic catheter was passed via an iliac conduit into the aneurysm sac of ten consecutive patients undergoing endovascular aortouniiliac repair. This was connected to an external pressure transducer allowing pressure monitoring during and for 24 h after the procedure. Flow was monitored in the SFA by insonation with a 2-MHz Doppler ultrasound probe. No technical defect was found in the deployment of seven of ten stents. Aneurysm sac pressure as a percentage of systolic blood pressure is shown in the *Table*.

	Predeployment	Postdeployment	Completion	24 h after operation
Aneurysm pressure (% systolic pressure)	109 (95–121)	59 (38–86)	41 (34–75)	52 (27–73)

Values are median (range)

In three cases technical problems were detected. In two patients the aneurysm sac pressure rose towards completion. Poor SFA flow was detected in one and contrast injected into the aneurysm sac revealed incomplete iliac occlusion, requiring open ligation. The second had good SFA flow and contrast injection revealed large patent lumbar vessels. Contrast injection at 24 h revealed complete exclusion of the sac. In a further patient incomplete stent deployment was detected by a rise in sac pressure to systolic pressure after balloon deflation.

Monitoring aneurysm pressure in combination with SFA Doppler flow can detect complications of endovascular aneurysm repair which can be corrected at operation.

Longitudinal aneurysm shrinkage following endovascular aortic aneurysm repair is a source of intermediate and late complications

J. Brennan, J. Martin, D. A. Gould, R. D. Edwards, A. Bakran, G. L. Gilling-Smith and P. L. Harris, *Royal Liverpool University Hospital, Liverpool, UK*

Successful endovascular aortic aneurysm repair results in thrombosis and shrinking of the sac, observed as a reduction in maximum transverse diameter (known as D3) with serial scanning. There are, however, no published data relating to alterations in the longitudinal parameter from renal arteries to aortic bifurcation (known as H3).

Patients undergoing endovascular aortic aneurysm repair were followed up by the EUROSTAR protocol, with regular computed tomography and angiography. Minimum 3-month follow-up (median 12 (range 3–18) months) has been completed in 25 patients. Aneurysm morphology was analysed according to serial changes in H3 and D3, with changes of more than 5 mm and greater than 2 mm respectively being considered significant.

Reduction in H3 was observed in 17 patients, of whom eight had a concurrent fall in D3. Reduction in D3 alone was only seen once. Progressive kinking of the stent graft was seen in seven patients, all with combined reduction in H3 and D3, and was associated with dislocation of the stump of a bifurcated system in two. In the eight patients with H3 reduction alone there was one distal endoleak and one iliac limb thrombosis. The four complications were salvaged by secondary endovascular means (three) and surgery (one).

Following endovascular aortic aneurysm repair, D3 reduction occurs less commonly than H3 reduction, and is not necessarily a favourable observation. The previously unreported phenomenon of longitudinal shrinkage (H3 reduction), both in isolation and in combination with transverse shrinkage (D3 reduction), was associated with a significant complication rate.

Significance of endoleaks after endovascular aneurysm repair

G. L. Gilling-Smith, on behalf of the EUROSTAR collaborators

The presence of an endoleak after endovascular repair of an abdominal aortic aneurysm (AAA) may be considered to represent failure of treatment since it signifies persistent or new communication between the circulation and the aneurysm sac. However, the relationship between endoleak, continued aneurysm expansion and late aneurysm rupture remains unknown.

Between May 1994 and June 1997, endovascular repair of AAA was attempted in 430 patients. Ten patients required conversion to open operation and a further 12 died within 30 days. The remaining 408 patients were followed for a median of 10 (range 1–36) months. The presence or absence of endoleaks and changes in the maximum transverse diameter of the aneurysm (MTD) were determined by serial contrast-enhanced computed tomography (CT) at 1, 3, 6, 12, 18 and 24 months after operation.

Endoleaks were observed on completion angiography and/or predischarge CT in 66 patients (16 per cent). A further 27 patients developed endoleaks during follow-up. Twenty-four leaks closed spontaneously, 27 were treated by additional endovascular intervention and three by open operation. One late rupture following development of a midgraft leak was successfully treated by open operation. Overall there was a progressive reduction in MTD during follow-up. However, an increase in MTD was observed in more than 20 per cent of patients at 12 months and this occurred significantly more frequently in patients with endoleaks (*Table*).

	No endoleak ($n = 141$)	Endoleak ($n = 42$)
MTD increasing*	11	53†
MTD decreasing*	73	40†
No change in MTD*	16	7†
Mean (s.d.) change in MTD (mm)	−5·1(7·2)	2·1(10·7)

*Values are percentage of patients; changes in MTD 12 months after endovascular repair of AAA; †$P < 0{\cdot}01$ (χ^2 test)

Continued expansion of the aneurysm is more likely in patients with endoleaks but infrequently leads to aneurysm rupture within a year of surgery. Further follow-up is required to evaluate the long-term fate of these aneurysms and to determine if the natural history is influenced by secondary closure of endoleaks.

Management of patients with failed endovascular stents

M. K. Lingam, M. Murphy, J. Moss, A. J. McKay and R. O. Quin, *Gartnavel General Hospital, Glasgow, UK*

Percutaneous transluminal angioplasty (PTA) with endovascular stenting is now commonly used in the treatment of aortoiliac occlusive disease. There are limited data on the long-term outcome of patients in whom stenting fails. A retrospective analysis of all patients who underwent stenting in whom the treatment failed has been carried out.

Between July 1993 and July 1996, a total of 80 patients had iliac stents inserted. In 19 patients the stent failed. There were 14 women and five men with a mean age of 55 (range 35–92) years. Fifteen presented with intermittent claudication and four with rest pain. All patients had aortoiliac occlusive disease which on arteriography was suitable for PTA. Six patients had Palmaz 294 stents, seven patients had kissing Palmaz 394 stents and six had wall stents. In eight patients the stent blocked immediately; radiological salvage was possible in four with good symptomatic outcome. In the other four patients, arterial reconstruction surgery was performed. Only one patient had a successful outcome and three eventually required amputation of the lower limb. In 11 patients the stents blocked at between 1 month and 4 years. In two, radiological salvage was attempted but failed and arterial bypass surgery was performed which was successful in one. Of the remaining nine patients who underwent arterial reconstructive surgery, six remain symptom free and three still have claudication.

Although stenting of iliac disease is widespread, experience suggests that complications are not uncommon. Surgery rather than further radiological intervention is usually needed.

Registry of Endovascular Treatment of Aneurysms: first year's results

S. Thomas, *on behalf of the Joint Working Party of the Vascular Surgical Society of Great Britain and Ireland*

The feasibility of endovascular repair of abdominal aortic aneurysms has been proven. Until the safety and efficacy of the technique has been established, its introduction into clinical practice needs to be carefully evaluated.

The Registry of Endovascular Treatment of Aneurysms (RETA) is based on a simple form which is machine readable. Between January and December 1996, a total of 139 forms were received from the 12 centres in the UK performing this technique. A median of nine (range 1–32) procedures were performed per centre and all involved a vascular surgeon and an interventional radiologist. Twelve aortic tube devices, 63 aortobiiliac devices and 64 aortouniiliac devices with additional crossover grafts were used. Forty-eight patients were considered unfit for conventional surgery.

At the end of the initial procedure 101 aneurysms (73 per cent) were successfully excluded with no complications. Ten patients required conversion to open repair and 21 required additional endovascular or surgical procedures. At 30 days, 118 aneurysms (85 per cent) were excluded or had been repaired. There were eight persistent leaks (6 per cent), one amputation and 13 deaths (9 per cent). The death rate was related to the fitness of the patient (7 per cent fit and 15 per cent unfit), type of device (4 per cent for tube or bifurcation devices *versus* 15 per cent for aortouniiliac and crossover) and need for conversion (50 per cent).

The preliminary results of the Registry support the need for continued evaluation, especially in the longer term. The short-term results support the proposal for a randomized trial of endovascular *versus* conventional repair in fit patients and endovascular repair *versus* conservative treatment in unfit patients. The appropriateness of conversion following failed endovascular repair needs careful consideration in unfit patients.

Popliteal vein reflux reduces the healing of chronic venous ulcer

Sir

I enjoyed the article by Brittenden *et al.* (*Br J Surg* 1998; **85**: 60–2) in which there was reference to work from our department regarding management of patients with venous ulceration with saphenous and perforator incompetence alone[1]. These patients were healed by ligation of the incompetent saphenous system. No perforator ligation was performed as incorrectly stated by the authors. I think this is an important distinction.

Predicting changes in the distribution of sweating following thoracoscopic sympathectomy

Sir

Andrews and Rennie (*Br J Surg* 1997; **84**: 1702–4) reiterate the myth that, in the treatment of palmar hyperhidrosis, it is necessary 'to divide, or ablate with diathermy, the second, third and possibly the fourth thoracic sympathetic ganglia'. The sympathetic nerves supplying the upper limb arise from the second to the sixth spinal thoracic segments. They join the sympathetic trunk after either synapsing in, or passing through, the segmental thoracic ganglia. They reach the upper limb by joining somatic nerves arising from the fifth cervical to the first thoracic spinal segments, i.e. the brachial plexus. It follows that they are present in the sympathetic trunk between the first and second thoracic ganglia. Division of the sympathetic trunk on the second rib will interrupt all sympathetic outflow to the hand except that which might pass through the nerves of Kuntz or the intercostobrachial nerve.

It has always been my practise to treat palmar hyperhidrosis by division of the sympathetic trunk on the second rib with scissors. To date, the operation has never failed to produce an immediate cure. By restricting the use of diathermy to the inferior end of the divided sympathetic trunk no patient need experience the unnecessary complications of ptosis or miosis.

Author's reply

Sir

I am grateful to Mr Collin for his response to our paper and agree that to achieve dryness of the hand a T2 sympathectomy alone, either by diathermy ablation or scissor dissection, is adequate. It had been our practice previously to perform a T2–3 sympathectomy, but we are now of the opinion that a T2 sympathectomy alone is adequate.

The reason we had previously been performing T2–4 sympathectomies was to achieve a simultaneous dryness of the axilla as well as the hand. We have found consistently that a T2–4 sympathectomy achieves about 80 per cent dryness of the axilla as well as the inevitable complete dryness of the hand.

However, as stressed in our paper, the risk of performing a more extensive, i.e. T2–4 sympathectomy, is the higher incidence of compensatory sweating, and we now recommend a T2–3 sympathectomy alone for hyperhidrosis of the hand and axilla.

Hereditary breast cancer

Sir

We read with interest the recent Review (*Br J Surg* 1997; **84**: 1334–9) on hereditary breast cancer, but feel that an important area was neglected, namely the management of patients with breast cancer in whom a mutation in the *BRCA1* or *BRCA2* gene has been identified. Hill *et al.* report the risk of breast cancer to be as high as 87 per cent by the age of 70 years in women with the *BRCA1* mutation, and up to 87 per cent by the age of 80 years with the *BRCA2* mutation. Breast surgeons will undoubtedly be referred an ever-increasing number of women with breast cancer who are either known or are subsequently found to carry such a gene mutation. It has also been reported recently that breast carcinoma in these patients is of a differernt histological type and higher grade than that in controls[1]. Should these patients be treated differently? Do they have a higher chance of local recurrence following conservation, and do they have a higher rate of contralateral breast cancer? The answers to these questions are presently unknown.

The lifetime risk of subsequent ovarian cancer in such patients is said to be 50–60 per cent (references 16 and 30 in article). Ovarian ablation as adjuvant therapy for breast cancer in premenopausal women has been shown to have similar efficacy to chemotherapy in terms of both event-free and overall survival[2]. A survival benefit has been demonstrated for ovarian ablation plus adjuvant chemotherapy rather than adjuvant chemotherapy alone for oestrogen receptor positive tumours[3].

A logical approach to adjuvant therapy in patients with *BRCA1* or *BRCA2* associated breast cancer would be to employ laparoscopic oophorectomy which could, at the same time, potentially reduce the risk of subsequent ovarian cancer.

Laparoscopy for the impalpable testis

Sir

Godbole *et al.* (*Br J Surg* 1997; **84**: 1430–2) record the continuing use of the inguinal canal as a recognized route for the exploration of an impalpable testis and reference three recent papers in which this route had been used in 43 boys, with a negative result, before referral to a paediatric unit. We must now hope that the advice of all these authors to regard this practice as 'unjustified' will be generally accepted.

Since the work of La Roque[1] in 1931 demonstrated its defects, it has been general experience that exploration for an impalpable testis through the inguinal canal is frequently unsatisfactory; this is because access to the intra-abdominal testis and the tethered retroperitoneal testicular vessels is so restricted. Frustration with this poor access and experience with Henry's approach to the femoral hernia led (in prelaparoscopy days) to the use of a preperitoneal approach. Using a Weir muscle-splitting incision gave excellent access to a testis some distance above the internal abdominal ring and made it easy to mobilize apparently short testicular vessels[2].

The authors and others have shown how helpful laparoscopy can be in selecting patients for whom exploration is useful and it is then well worthwhile to consider use of the preperitoneal approach. We note that they achieved 'standard' orchidopexy in 25 of 32 boys with an intra-abdominal testis and only used the Fowler–Stephens procedure on six occasions. In view of the difficulties that attend orchidopexy for these testes, it would be interesting to know the route used in the 25 orchidopexies and the long-term results.

Helicobacter pylori and peptic ulcer surgery

Sir

I read with interest the views of Chung and Li (*Br J Surg* 1997; **84**: 1491–2) on the impact of *Helicobacter pylori* on peptic ulcer disease. In particular, it was useful to contrast the implications for surgery between the clear efficacy of *H. pylori* eradication as secondary prevention for ulcer haemorrhage and the balanced caution expressed regarding the long-term outlook for anti-*H. pylori* and endoscopic therapies for gastric outlet obstruction.

On currently available evidence, however, the authors may have overstated the case by implicating *H. pylori* in the causation of perforated ulcers and in their conclusions concerning the effect of *H. pylori* eradication on perforated ulcers. Until more definitive studies are performed, the aetiological role of *H. pylori* in perforated ulcer will remain controversial. The only adequately controlled study demonstrated no increase in prevalence of *H. pylori* infection (47 per cent of perforated ulcers *versus* 50 per cent of controls)[1]. Two other studies have demonstrated slightly higher rates of 24 of 29[2] and 51 of 73[3], but without including control groups. In contrast to the situation in ulcer bleeding[4], there are no trials (randomized or otherwise) illustrating that *H. pylori* eradication alters the natural history of ulcer perforation. While it seems reasonable to give anti-*H. pylori* therapy to those with infection, it is essential to recognize that the recommended approach of patch repair and antibiotics is not yet supported by trial data. Recurrent ulceration and perforation occurs after simple patch repair even if pharmacological acid suppression is continued[5,6]. In the author's own series 16 per cent of patients had no easily reversible risk factor (*H. pylori* or non-steroidal anti-inflammatory drugs) showing that *H. pylori* eradication will not affect this substantial subgroup[3].

Well conducted trials have now been performed in the management of patients with bleeding ulcers[4], and it would be appropriate for similar studies to define the roles of surgery, *H. pylori* eradication and pharmacological acid suppression in the treatment of perforated ulcer.

Early effect of carotid endarterectomy on arterial blood pressure measured with an ambulatory monitor

Sir

We were interested to read the article by Dodds *et al.* (*Br J Surg* 1997; **84**: 1104–6) on the effects of carotid endarterectomy on arterial blood pressure 2 weeks after surgery but disappointed they did not provide more information about the surgical techniques used.

They suggested that the fall in blood pressure following carotid endarterectomy was a result of increased firing of the carotid sinus baroreceptors, as in the postoperative period there would be an increased lateral pressure on the carotid sinus wall (loss of Venturi effect) and an increased radius, thereby increasing sinus wall tension (Law of Laplace, T = PR). The diameter of the carotid sinus often increases after endarterectomy without patching[1], and Eastcott[2] postulated that the use of a patch in closure would widen the sinus even further, thereby creating a more dramatic reduction in blood pressure. The type of material used may also be of relevance in affecting compliance. It is therefore important to know whether patching was used for the ten patients in this study. They also mention that they preserved the carotid sinus nerve 'where possible' and it would be useful to know how often this was not possible and if these patients also showed a fall in blood pressure after 2 weeks. Finally, we wonder whether there are long-term results to compare their results with previous studies, which found no long-term alteration in blood pressure[3].

Author's reply

Sir

The haemodynamic and biomechanical effects of carotid endarterectomy on carotid sinus function and blood pressure regulation are the result of a complex interaction between at least three factors: the loss of the pressure gradient across the stenosis, the mechanical effect of a patch angioplasty, and possible operative damage to the carotid sinus nerve. Two methods are commonly used to measure the effect of surgery: (1) measurement of carotid sinus sensitivity such as change in heart-rate in response to reduced neck pressure or altered arterial pressure; and (2) measurement of blood pressure. In their studies Angell-James and Lumley[1], and Dehn and Angell-James[2] both measured carotid sinus sensitivity and both showed three types of response after surgery with an inverse relationship between carotid sinus nerve function and blood pressure. However, such studies are difficult to repeat in groups of patients large enough to allow the effect of individual factors to be analysed over a long follow-up interval. The alternative option is blood pressure management, which is itself complicated by the variability of blood pressure, and the problems this introduces for single measurements. Our primary finding was that, if ambulatory blood pressure measurement is used, the effect of blood pressure variability is reduced and only small groups of patients are required to show a significant change in the mean blood pressure. The study was not powered to show the separate effects of stenosis severity, patching or nerve preservation, and so to avoid a type II error the data on which patients were patched were not presented. In considering the mechanical effect of endarterectomy the stress–strain relationship for arteries is non-linear, and in fact shows an increase in stiffness with strain. It is therefore expected that increased arterial diameter secondary to increased pressure or a patch angioplasty will result in reduced compliance[1]. The effect on carotid sinus function is not so predictable as it depends on whether the carotid sinus measures dynamic or static strain[3], and the degree of long-term adaptation. While a nerve-preserving dissection was employed, we did not measure carotid sinus sensitivity and so cannot comment on which patients suffered nerve damage. As with previous studies, however, we did observe some patients who had only a small fall in blood pressure, and others in whom it was much more marked. Finally, the evidence in the literature about the long-term effect of carotid endarterectomy requires careful interpretation. Dehn and Angell-James[2] showed no change in mean blood pressure for the whole group at 6 months but there was a measurable long-term effect on carotid sinus sensitivity for individual patients. Further evidence for there being two separate groups of patients is given by Hirschl *et al.*[4], who showed that for longer follow-up, an increase in carotid sinus sensitivity is associated with reduced blood pressure, while a decrease in carotid sinus sensitivity was associated with increased incidence of major vascular events.

We accept the validity of the points raised but recommend that a larger study employing measurements of both carotid sinus sensitivity and ambulatory blood pressure is required. Such a study would appear to be worthwhile if, for some patients at least, carotid endarterectomy is associated with a long-term reduction in the risk of a major vascular event.

Book reviews

Video-Book. Per Urethral Endourological Operative Techniques (For Rigid Endoscopies Only)

S. S. Bapat (ed.). 250 × 225 mm. Pp. 325. Two videotapes (408 min). Illustrated. 1996. Tuttlingen: Karl Storz. Price not supplied.

Professor Bapat has put a great deal of work into producing this video book. As indicated in the title, the book does not cover the entire field of endourology; there is no chapter on percutaneous nephrolithotomy. The book is also restricted to endourological techniques with rigid instruments; flexible cystoscopy and flexible ureteroscopy are not covered. It is directed towards the urological higher surgical trainee and would be of most benefit to a trainee starting his/her urology career. The chapters are written to coincide with the video; this is the concept of the video book. In this respect, the work is virtually unique. Its strength lies in the enormous amount of clinical material covered in the video section. All common endourological procedures, other than percutaneous nephrolithotomy, are covered and the reader is able to familiarize him or herself with standard endoscopic procedures. The endoscopic features of a wide range of urological conditions have been captured on video. The weaknesses are in the quality of the sound and, in places, the picture. The video is on two cassettes with a viewing time of 408 min, which is probably too long. The continuous background music can become tedious, but the chapters on transurethral prostatectomy and ureteroscopy are particularly good. Despite the rather amateur quality, there is a great deal of interesting clinical material presented, but it is of limited appeal to the practising urologist with experience in endourological techniques. There are likely to be more publications of this type to help demonstrate endourological procedures to the urological trainee and to familiarize practising urologists with new techniques.

Case Presentations for the MRCS and AFRCS (three volumes)

P. Hornick, J. S. P. Lumley, P. A. Grace (eds). 209 × 130 mm. Pp. 199 pp (vol. 1); 188 pp (vol. 2); 191 pp (vol. 3). Illustrated. 1997. Oxford: Butterworth-Heinemann. £14.99 per volume.

This three-volume book contains 111 case presentations intended for candidates for the MRCS and AFRCS examinations. Each case history is followed by up to ten questions which are then answered at an appropriate level by contributors, many of whom are national authorities in their field. The range of subjects chosen corresponds with the MRCS/AFRCS syllabus.

Is there a need for such a book? Although I was initially sceptical, after reviewing the volumes I am more convinced that this work will be a useful addition to the reading material for basic surgical trainees. The case presentations could be used in a number of ways. For instance, after reading the standard texts, candidates may find it useful to put their knowledge to the test by reading the case histories and then attempting to answer the questions. A comparison may then be made between their own answer and the book answer. The book will also come in handy for last-minute revision and, in addition, it provides insight into the level of knowledge required for examination. In this context I suggest that the 'height of the hurdle' set by the contributor in a few of the answers is a little higher than I would expect for the MRCS and AFRCS examinations. This is a small criticism. The editors and contributors should be congratulated on producing such a valuable book and I have already recommended it to senior house officers preparing for the examination. I would suggest tentatively that examiners for the MRCS and AFRCS examinations might also find it interesting to browse through.

Tropical Surgery – A Vademecum Series Book

R. V. Cohen and F. Aun (eds). 215 × 141 mm. Pp. 337. Illustrated. 1997. Basel: Karger Landes Systems. US$49.

It is difficult to find such an interesting book about the main surgical diseases of the tropical and subtropical areas of the world, although millions of inhabitants of those areas are still suffering from the diseases. After reviewing this handbook of *Tropical Surgery*, I have to accept that this is one of a limited number of very high standard books. Each chapter is generally well written with excellent figures, and covers important and relevant information. The format of this handbook allows readers to spend only a short period of time in understanding clinical features, how to make a diagnosis and how to grasp the principles of surgical management. The content is up to date and the examples of imaging studies are very clear. Moreover, at the end of each chapter, the authors provide a list of suggested reading with a short commentary. I consider this book to be splendid and that not only a surgeon, but also a general practitioner or even a physician, would benefit from reading it.

Atlas of Surgical Technique in Urology

E. D. Whitehead (ed.). 310 × 235 mm. Pp. 578. Illustrated. 1997. Philadelphia, Pennsylvania: Lippincott-Raven. £134.25.

This volume, with an exclusively North American authorship, is presented as an illustrated textbook of operations. The aim of the editor was to produce an atlas of operations based on well written operative reports and accompanying illustrations. This has resulted in a somewhat diverse style of writing and considerable variability in the detail of each operative description. The atlas certainly allows the urologist to 'participate in the operation described', but some of the chapters do not always provide sufficient detail to enable the urologist, who has perhaps only seen the procedure once or twice, to read up on the operation and then perform it. One or two of the illustrations are a little eccentric and superfluous, but for the most part they are of good quality. There are one or two surprising omissions which perhaps reflect North American practice (for example, removal of a staghorn calculus by extended phyelolithotomy and radial nephrotomies), and one or two surprising inclusions (open pyelolithotomy, anatrophic nephrolithotomy and balloon dilatation of the prostate). It is surprising that there is no mention of endoscopic techniques for ureteropelvic junction obstruction; the only description of open surgery for ureteropelvic junction obstruction is that of a Hynes Anderson pyeloplasty without any clear attribution to the original authors in the description of the procedure. For me, the book does not quite succeed in achieving its objectives. It is a welcome addition to my own library, but the acid test is 'would I buy it for the department?' The answer to this question has to be 'no' as there are competing texts which are of more value to the UK urologist.

Endosurgery (CD-ROM)

J. Toouli, D. Gossot and J. G. Hunter (eds). Illustrated.
1997. New York: Churchill Livingstone. £185.

This CD-ROM package is based on a comprehensive textbook first published by the editors in 1996, and which provides up-to-date information on minimal access surgical procedures performed laparoscopically, thoracoscopically and endoscopically. The package comprises the entire text on disk, along with illustrations and tables. The contents are clearly of topical interest and are enhanced by the provision of a MEDLINE database from key journals in the field covering the past 5 years. The package is easy to use and provides an on-line user's guide and tutorial for the computer illiterate. One of the potentially attractive features is the accompanying 38 video clips which are intended to demonstrate key surgical procedures. These 50–60 s 'vignettes' do not uniformally lend themselves to this form of postgraduate teaching, and the quality of some of these makes it difficult for the user to grasp the rudimentary details of the operative procedure. Endosurgery is a rapidly changing area which lends itself well to this format, although it may well require a little more fine tuning before the authors and publishers have a package that will appeal to the surgical community.

Instructions to authors

The British Journal of Surgery publishes original articles, reviews and leading articles. All manuscripts are submitted to editorial review.

An article is reviewed for publication on the understanding that the work it reports has not been submitted simultaneously to another journal, has not been accepted for publication elsewhere and has not already been published. **Any detected attempt at dual publication will lead to automatic rejection and may prejudice acceptance of future submissions.** To avoid subsequent embarrassment, please submit with your manuscript copies of any other papers, either published, in press, or submitted for consideration elsewhere, which relate to the same subject. It is essential that you submit any other publications or submissions using the same data set to the Editors to allow assessment of any potential overlap with the submission to the Journal. Indicate on the title page whether the paper is based on a previous communication to a society or other meeting. Articles and their illustrations become the property of the Journal unless rights are reserved before publication.

Send three copies of original articles and other editorial matter to: The Editor, *The British Journal of Surgery*, Blackwell Science Ltd, 25 John Street, London WC1N 2BL, UK. Telephone: 0171 404 1831. Facsimile: 0171 404 1927. Books for review should be sent to the same address.

A covering letter must accompany all submissions and must be signed by all authors. State in the covering letter whether an abstract of the work has been published and give an appropriate reference on the title page. Disclose in the covering letter any potential or actual personal, political or financial interest you may have in the material, information or techniques described in the paper. The decision to publish or withhold such information will be made by the Editors. Acknowledge all sources of financial support for the work. The first named author is responsible for ensuring that all authors have seen and approved the manuscript and are fully conversant with its contents. The Journal accepts the criteria for authorship proposed in the *British Medical Journal* (*BMJ* 1994; **308**: 39–42). When a paper has many authors (i.e. more than six), you may be asked to justify the inclusion of all names listed. Results of multicentre studies should be reported under the name of the organizing study group. Methods of recognizing contributors have been proposed (*Lancet* 1995; **345**: 668).

Disks

Following final approval of articles, you will be asked to submit the accepted version on disk. These should be IBM-compatible. An accurate hard copy must accompany each disk, together with details of the type of computer used, software, and disk system if known. **Do not justify.** Please send us digital versions of your figures. Ideally, these should be sent in native format or WMF if created in Windows. Files saved as PS, EPS, GIF and TIF may also be used, but please note that it may not be possible to modify them. Avoid using tints if possible; if they are essential, try to make them coarse. Further details can be obtained from the publisher. Disks will not be returned to authors.

Rejected manuscripts and illustrations will not normally be returned.

Ethics

The Journal publishes all material relating to human investigation and animal experiments on the understanding that the design of the work has been approved by local ethics committees or that it conforms to standards currently applied in the country of origin. The Journal further reserves the right not to publish an article on the grounds that appropriate ethical or experimental standards have not been reached. Written consent must be obtained from the patient, legal guardian or executor for publication in *The British Journal of Surgery* of any details or photographs that might identify an individual. Submit evidence of such consent with the manuscript.

Preparation of manuscripts

The British Journal of Surgery subscribes to the policy of uniform requirements for manuscripts, which is designed to permit authors to resubmit papers to journals without extensive recasting. Authors are advised to consult the *New England Journal of Medicine* 1997; **336**: 309–15, or to obtain the leaflet 'Uniform Requirements for Manuscripts Submitted to Biomedical Journals' from The Editor, *British Medical Journal*, BMA House, Tavistock Square, London WC1H 9JR, UK (cost £1.00 per copy).

Authors are responsible for the accuracy of their report including all statistical calculations and drug doses. **When quoting specific materials, equipment and proprietary drugs, state in parentheses the brief name and address of the manufacturer.** Failure to do so will result in delay in publication as the Journal believes that this information is essential for any reader who wishes to obtain similar material. Generic names should normally be used.

Original articles

Original articles should normally be in the format of introduction, methods, results, discussion. Each manuscript must have a 200-word structured abstract. Lengthy manuscripts are likely to be returned for shortening. The discussion in particular should be clear and concise and should be limited to matters arising directly from the results. Avoid discursive speculation. **Randomized clinical trials** should be clearly identified as such in the title and abstract.

Reviews

The Editorial Board of *The British Journal of Surgery* encourages submission of review articles on topics of interest to its readers. Any topic will be considered, but priority will be given to those addressing a major current problem. The author of each accepted review will receive an honorarium. Potential authors are advised to contact: Mr J. A. Murie, University Department of Surgery, The Royal Infirmary, Edinburgh EH3 9YW, UK.

Leading articles

The Editors commission signed leading articles which are 600–900 words in length and address controversial topics of current interest. They should be supported by no more than ten key references. Submissions may be subjected to external review and assessment by the Editorial Board before acceptance. The Editors retain the right to alter style and shorten material for publication. An honorarium is payable on publication.

Correspondence

The Editors welcome topical correspondence relating to articles published in the Journal. Letters should not exceed 250 words and should be typed double-spaced.

Typescripts

Manuscripts must be clearly reproduced with adequate space for editorial notes. **Type or print the text on one side of sheets of A4 paper (210 × 297 mm) with double spacing and 4-cm margins. Manuscripts that do not conform to these requirements will be returned to you for recasting.** Begin each section (abstract, introduction, patients and methods, results, and discussion) on a new page.

Title page

On the title page give: (1) the title of the article; (2) the name and initials of each author; (3) the department and institution to which the work should be attributed; (4) the name, address, and telephone, facsimile and e-mail numbers of the author responsible for correspondence and to whom requests for reprints should be addressed; (5) sources of financial support; and (6) the category in which the manuscript is being submitted (original article, review etc.).

Abstract

This should be not more than 200 words on the second page of the manuscript and be presented in a structured format. **Background:** state why the study was done, and its main aim; **Method:** describe patients, laboratory material and other methods used. Clearly identify the nature of the study: randomized controlled trial, retrospective review, experimental study, etc. **Results:** state the main findings of the study; include important numerical values. **Conclusion:** state the main conclusion drawn from the results. Controversial or unexpected observations may be highlighted, but keep this section brief. Write the abstract in clear prose.

Tables and illustrations

Submit three copies of all illustrations and tables. Type each table on a separate page with an appropriate brief title. Line drawings are acceptable as clear black on white graphics, computer printout or photocopies. Submit radiographs, photomicrographs, etc unmounted in the form of glossy prints, original transparencies or negatives. If you include photocopies, they should be of sufficient quality to enable the Journal's referees to judge their content and value. Label each illustration on the reverse side giving its number (to correspond with its reference in the text) and the name(s) of the author(s); indicate the top of the illustration. Include a measure of magnification of photomicrographs. Illustrations should be drawn and labelled appropriately for reduction to one or two column widths of the Journal. Include explanations of symbols and shading in the legend. Survival curves should be accompanied by a table giving the actual numbers of patients involved. Include in the legends to illustrations and the footnotes to tables brief but comprehensive explanations of all the information presented. Look at recent issues of the Journal for examples of accepted layout. If a table or an illustration has been reproduced from a published work give the original source in full. Obtain permission to use published work from the original author and the publisher before submission.

Abbreviations

Use abbreviations sparingly. Terms that are mentioned frequently may be abbreviated but only if this does not impair comprehension by the reader. Use abbreviations consistently throughout the text and clearly define each one on first use.

Numbers and units

Use the decimal point, not a comma, e.g. 5·7. Use a space and not a comma after thousands and multiples thereof, e.g. 10 000. Use SI units (International System of Units) except for the measurement of blood pressure (mmHg). Where measurements were made in non-SI units, give the actual values and units, with SI equivalents inserted in parentheses at appropriate points.

Statistics

For detailed guidance on the handling of statistical material, consult *Br J Surg* 1991; **78**: 782–4. In evaluating a manuscript the Editors and statistical referees will consider the design of the study, the presentation and analysis of data and the interpretation of results.

Design

Set out clearly the objectives of the study, identify the primary and secondary hypotheses, and the chosen end-points, and explain the rationale for the choice of sample size. Investigators embarking on randomized controlled studies may wish to consider the CONSORT statement (*JAMA* 1996; **276**: 637–9).

Presentation

Whenever possible use graphical presentation to illustrate the main findings of a study. The use of standard deviation and standard error should be clearly distinguished. Do not use the ' ± ' symbol; these statistics should be presented in parentheses after the mean value.

Analysis

Clearly describe which methods were used for which analyses; any methods not in common usage should be supported by references. Report results of statistical tests by stating the value of the test statistic, the number of degrees of freedom and the P value, e.g. '$t = 1{\cdot}34$, 16 d.f., $P = 0{\cdot}20$'.

Actual P values should be reported to two decimal places, especially when the result is not significant, rather than stating 'not significant'. Whenever possible, the results of the primary analyses should be reported using confidence intervals instead of, or in addition to, P values.

Interpretation

Do not confuse statistical significance with clinical significance. In particular, 'negative' findings should be interpreted through the use of confidence intervals.

Beware of placing undue emphasis on secondary analyses, especially when they are suggested by an inspection of the data.

References

Type the references with double spacing in the Vancouver style (see above: Uniform Requirements for Manuscripts Submitted to Biomedical Journals). Reference to abstracts from meetings is discouraged. Reference to unpublished communications will not be accepted. Cite personal communications in the text, in parentheses. The first author is responsible for confirming the acceptability of the material quoted with the originator.

In the text, number the references consecutively by superscript: ^{1} or $^{1-3}$. References cited only in tables or figures should be numbered in sequence according to the first mention of the table or figure in the text. The sequence for a standard journal article should be: author(s); title of paper; journal name abbreviated as in Index Medicus (written in full if no abbreviation is quoted); year of publication; volume number; page numbers. For example: De Bolla AR, Obeid ML. Mortality in acute pancreatitis. *Ann R Coll Surg Engl* 1984; **66**: 184–6. The sequence for the chapters of a book should be: author(s); chapter title; editors; book title; place of publication; publisher; year of publication; page numbers. For example: Calenoff L, Rogers L. Esophageal complications of surgery and lifesaving procedures. In: Meyers M, Ghahremani G, eds. *Iatrogenic Gastrointestinal Complications*. New York: Springer, 1981: 123–63.

British Journal of Surgery 1998, **85**, 577–579

Leading articles

Cystic tumours of the pancreas

Cystic tumours of the pancreas comprise neoplasms of epithelial and other origin and congenital pseudotumours. Epithelial tumours make up 90 per cent of cystic tumours of the pancreas[1]. Recently these tumours have been classified with a system that defines each tumour with a single name and a precise histological grade[2]. The commonest epithelial tumours are benign cystadenomas (serous or mucinous) and cystadenocarcinomas, which together represent three quarters of all these cystic tumours[1,3].

After discovery of a cystic lesion in the pancreatic region there are three necessary diagnostic steps: (1) to confirm the intrapancreatic origin of the cyst, (2) to rule out the diagnosis of pseudocyst and (3) to identify those cystic tumours which should be resected because of actual or potential malignancy. The clinical context and the history can be conclusive in this sequence. Ultrasonography is valuable for detection of cystic lesions. Spiral computed tomography (CT) with intravenous contrast enhancement is the examination of choice and is usually sufficient for anatomical localization and diagnosis in the majority of cystic tumours. Arteriography does not contribute to diagnosis and occasionally study of cyst fluid, endoscopic ultrasonography, retrograde pancreatography or magnetic resonance pancreatography, and endoscopic pancreatoscopy may be helpful.

Serous cystadenomas are the commonest single type of cystic tumour (32 per cent)[1,3]. They are characterized by a microcystic appearance with more than six cysts of less than 2 cm in diameter[4]. In addition, there may be central calcification, enhancement around microcysts or of septa, and larger cysts on the periphery of the lesions. Demonstration of these CT signs in typical cases is diagnostic. In practice, outside of centres experienced in pancreatic imaging[4,5] the diagnostic accuracy is between 20 and 40 per cent[1,6]. It is likely that accuracy will improve with the more widespread use of spiral CT. The microcystic component of small tumours of 3 cm or less is better demonstrated by endoscopic ultrasonography. Macrocystic forms are present in about 10 per cent of cases and lead to diagnostic difficulty. In this situation examination of cyst fluid can demonstrate typical epithelial cells rich in glycogen and very low levels of tumour markers[7].

Mucinous cystic neoplasms consist of mucinous cystadenomas and mucinous cystadenocarcinomas. They represent 44–49 per cent of cystic tumours[1,3]. The distinction of benign and malignant lesions can be made only by histological examination after pancreatic resection. The risk of malignant progression of mucinous cystadenomas is probably high but difficult to determine. These tumours typically consist of large cysts with septa, peripheral calcification and sometimes a solid intracystic component. Demonstration of a large multilocular cyst should lead to surgical resection without any other investigation. A large unilocular cyst without preceding pancreatitis and with an otherwise normal pancreas is most likely a mucinous pancreatic neoplasm. If there is a history of acute pancreatitis (which can complicate mucinous tumours), examination of cyst fluid can discriminate between tumour and pseudocyst. Biochemical examination of cyst fluid in mucinous neoplasms shows very low levels of pancreatic enzymes and high levels of tumour markers[7]. The presence of mucin-containing or malignant cells is conclusive. Nevertheless there remains a considerable risk of diagnostic overlap with pseudocyst; 9 per cent for mucinous cystadenomas and 15 per cent for cystadenocarcinomas[1]. This risk increases when the cystic tumour communicates through the pancreatic duct (7 per cent of cystadenomas and 10 per cent of cystadenocarcinomas).

Intraductal papillary and mucinous tumours have been defined recently, and represent 11 per cent of cystic tumours[1,3]. In these tumours the cysts are in fact dilated main pancreatic duct or secondary branches of the duct. The duct lining produces a mucus secretion which fills the duct lumen. The mucosa shows changes of adenoma with dysplasia, or adenocarcinoma. The duct dilatation may be demonstrated by endoscopic ultrasonography or CT and there is no evident obstructing lesion. Duodenoscopy typically shows mucus oozing from the major papilla, and pancreatography demonstrates numerous plugs in the dilated pancreatic ducts. These appearances make diagnosis of intraductal tumour difficult. Magnetic resonance pancreatography and pancreatoscopy may allow localization of the tumour; this may permit partial pancreatic resection.

Pseudopapillary and solid tumours represent 4 per cent of cystic tumours[1,3]. Despite their name, they contain cystic areas consisting of regions of haemorrhage and necrosis. The diagnosis should be considered when there is a large tumour with solid and cystic areas often with calcification, with a capsule, and presenting in a young woman or adolescent. Magnetic resonance imaging appears superior to CT for the diagnosis of these tumours[8].

Treatment of epithelial cystic tumours of the pancreas should be related to the histological grade. Serous cystadenomas are benign tumours; malignant serous cystadenocarcinomas are exceptional[9]. Conservative management is wholly justified for a well documented serous cystadenoma with no symptoms and without duct or vascular obstruction. The patient should be followed by annual ultrasonography because some tumours unpredictably develop complications. In other cases, pancreatic resection taking account of the benign nature of the tumour should be performed. Mucinous cystadenomas should be resected completely, which is often relatively straightforward given the preponderance of distal lesions (72–80 per cent). Cystadenocarcinomas are often resectable (up to 73 per cent[1]) but may involve the resection of neighbouring organs and, if necessary, the portal vein. These extensive resections are justified as the 5-year survival rate may exceed 50 per cent[1,10]. Adjuvant therapy should be considered for aneuploid tumours. Papillary and mucinous intraductal tumours should be resected to remove all the adenomatous or malignant mucosa, in order to avoid recurrence in the pancreatic remnant. Peroperative pancreatoscopy and frozen-section examination of the resection margin are useful in determining the extent of resection, which may need to be total. Finally, pseudopapillary solid cystic tumour should be considered potentially malignant and should be resected completely.

There remain several unanswered questions. Mucinous cystic tumours which communicate with the pancreatic duct are not clearly distinguished from intraductal tumours. The epidemiological differences between mucinous cystadenomas and cystadenocarcinomas call into question the link between these two lesions. The long-term outcome of the ductal system after partial pancreatectomy for intraductal tumours is unknown, as is the risk of subsequent metastases after resection of a pseudopapillary solid tumour; some cases have been reported.

Acknowledgements

The author acknowledges the contribution of Professor L. de Calan and Professor C. Partensky who are co-authors of the report to the Association Française de Chirurgie on cystic tumours of the pancreas, and of Mr C. D. Johnson who provided the English translation of this manuscript.

Skull radiographs and children with blunt head injury

Assessing children for possible intracranial injury following blunt head trauma often is difficult. Children with an impaired level of consciousness or focal neurological signs are relatively easy to identify, but many have non-specific symptoms of headache, vomiting or drowsiness, with no focal neurological signs. Such symptoms occur with and without intracranial injury and may be difficult to interpret. In the UK, skull radiographs are used widely to select children who have a skull fracture for admission to hospital or for computed tomography (CT) of the head. This is based on evidence from retrospective studies, notably that of Teasdale *et al.*[1], which suggests that a skull fracture is a risk factor for intracranial haematoma. However, this approach is not accepted universally[2,3], particularly because major intracranial injury may occur in children in the absence of a skull fracture; in the report by Teasdale *et al.*[1], 38 per cent of those with intracranial haematoma did not have a skull fracture.

Under the age of 2 years, the routine use of skull radiography is justified because of the high risk of non-accidental injury in this age group. The nature of the skull fracture and the presence of old injuries may be important clues as to the cause of the injury. It is in older children that the role of skull radiography is controversial.

The results of two relevant prospective studies have been published recently. One was a study of 9269 children with blunt head trauma who attended the Accident and Emergency Department at Alder Hey Children's Hospital in Liverpool[4,5]. Of these, 6011 had a skull radiograph; 161 (2·7 per cent) skull fractures were revealed. A head CT scan was carried out in children with a radiologically evident fracture and in those without a fracture if there were neurological indications for such a scan.

Almost a quarter (23 per cent) of the skull fractures were missed by accident and emergency surgical staff who assessed the initial radiographs, and there were nine false-positive diagnoses of fracture. Sixty-four patients with no neurological abnormality had a head CT scan because a skull fracture had been identified; only one scan showed an intracranial abnormality and this was of no clinical significance. Seventy-seven patients underwent head CT because of neurological abnormality and 16 scans showed an intracranial abnormality, four in children without a fracture. Four patients died, only one of whom had a skull fracture.

In summary, intracranial injury occurred in patients with or without skull fracture and all those with a clinically significant injury had neurological indications for CT. These indications were altered level of consciousness, focal neurological abnormality or persistent/progressive symptoms. For prediction of intracranial injury the sensitivities of skull radiography and neurological abnormality were 65 and 91 per cent respectively. The negative predictive values were 83 and 99 per cent respectively.

The second report, from St Louis Children's Hospital in Missouri, was a prospective study of 322 children with 'non-trivial' head injury, defined as injury associated with neurological symptoms or signs[6]. Fifty children (16 per cent) had a skull fracture; intracranial injury occurred in 27 (8 per cent), of whom 13 did not have a skull fracture. In general, the authors' conclusions and recommendations were in agreement with those of the Liverpool group, with the exception that Quayle *et al.* concluded that 16 of their 27 patients with intracranial injury were neurologically normal, defined as having normal mental status and no focal neurological abnormality. However, ten of these children were aged 2 years or more and all had one or more symptoms of brain injury, namely headache, vomiting, amnesia, dizziness or drowsiness. Using the Liverpool criteria, all of these patients would have been admitted to hospital and all those with a clinically significant intracranial abnormality would have had a CT scan.

These two reports support the argument that the skull radiograph is not a reliable triage tool for children following blunt head trauma. Although an intracranial injury is more likely to occur when the skull is fractured, severe injuries occur without a skull fracture and the skull radiograph cannot be justified rationally as a tool for diagnostic exclusion. Patients in whom symptoms of possible neurological injury, notably headache, vomiting and drowsiness, are the only abnormal findings should be observed in the accident and emergency department. Most will recover within a few hours and may be allowed home with written guidelines for recognizing and reacting to signs of evolving lesions. Those whose symptoms persist beyond 6–8 h should be admitted to hospital for further observation. If the symptoms continue and, particularly, if they become progressively more severe, an urgent head CT scan is indicated. A skull radiograph does not contribute to this care pathway and should be restricted to patients with suspected non-accidental injury, penetrating injury or depressed fracture.

Radiographs may continue to be requested by those who fear possible medicolegal consequences if, for example, a patient who is sent home from the accident and emergency department without having a radiograph is subsequently found to have an intracranial haematoma. There is no simple answer to this. The Bolam ruling (1957)[7] would support a practice accepted as proper by a 'responsible body of medical men'. The most recent authority on this, the House of Lord's decision in Bolitho (1997)[8], focuses on the risk/benefit ratio of an intervention. This is an arena which requires further legal exploration.

Review

Antibiotic prophylaxis in the initial management of severe acute pancreatitis

J. J. POWELL, R. MILES* and A. K. SIRIWARDENA

*University Departments of Surgery and *Medical Microbiology, Royal Infirmary of Edinburgh, Lauriston Place, Edinburgh EH3 9YW, UK*

Background The role of antibiotic prophylaxis in the initial management of patients with acute pancreatitis is an area of major controversy. Contrary to earlier clinical trials, recent experimental and clinical studies have accrued evidence that warrants reappraisal of current clinical practice. This article reviews these recent advances in knowledge.

Methods All papers derived from a Medline search for the years 1990–1997 inclusive using the text words 'acute', 'pancreatitis', 'antibiotic' and 'antibiotics' were studied. Additional papers were derived from reference lists within papers identified by the Medline search. Only experimental and clinical papers relevant to the issue of prophylactic antibiotic therapy in acute pancreatitis are included in the review.

Results and conclusion Current experimental evidence favours the use of prophylactic antibiotics in severe acute pancreatitis. The results of contemporary randomized clinical trials restricted to patients with prognostically severe acute pancreatitis have demonstrated improvement in outcome associated with antibiotic treatment.

The results of three prospective randomized clinical studies of antibiotic prophylaxis in severe acute pancreatitis provide evidence of a role for antimicrobial therapy as part of initial treatment in this condition[1–3]. Nevertheless, controversy persists about the strength of evidence for antibiotic therapy and in a recent review Barie[4] stated that 'the data are insufficiently strong to mandate prophylaxis or elevate it to the standard of care'. However, given the rapid rate of accrual of evidence, Barie's statement and the evidence base on which it was made require reappraisal. This need is made more pressing by the fact that if his statement were to be accepted widely, a potentially valuable therapeutic option in the management of a disease with relatively few specific treatment modalities could be lost. This article reviews recent experimental and clinical studies relating to antibiotic prophylaxis in acute pancreatitis.

Methods

A Medline search was carried out for the period 1990–1997 inclusive using the textwords 'acute', 'pancreatitis', 'antibiotic' and 'antibiotics'. In addition, a search using generic drug names was carried out to identify studies in which specific antibiotics were used. Articles identified from these two searches were studied. Further articles relating to the use of prophylactic antibiotics in acute pancreatitis were identified from the reference lists of papers identified previously through the Medline searches. Papers with data relating to antibiotic penetration into human pancreatic tissue, studies of prophylactic antibiotics in experimental acute pancreatitis and clinical trials in human acute pancreatitis were studied.

Paper accepted 12 January 1997

Bacterial involvement in acute pancreatitis

Local pancreatic infection occurs in 30 per cent of patients with severe acute pancreatitis and is associated with significant morbidity and mortality rates[5]. Although pancreatic infection comprises two somewhat distinct clinical entities, pancreatic abscess and infected pancreatic necrosis, the organisms found in each condition are generally similar[6–8]. Data relating to secondary microbial infection in acute pancreatitis are difficult to interpret and compare, because of the lack of standardization in nomenclature before the 1992 Atlanta consensus conference[9]. Earlier data are also affected by the difficulties of culturing anaerobic species. With these limitations in mind, microbiology results demonstrating organisms cultured from patients with infective complications of acute pancreatitis are shown in *Table 1*.

The important organisms appear to be aerobic Gram-negative bacilli, in particular *Escherichia coli*, with a significant number of cases involving *Enterococcus* spp. and *Staphylococcus* spp. Fungal infection is uncommon, but increased antibiotic usage may modify prevalence. Polymicrobial infection occurs more frequently in pancreatic abscesses than in infected pancreatic necrosis[6] and more often involves an *Enterococcus* sp.[13].

The recognition that colonic type bacteria frequently cause pancreatic infection has led to the theory that the gut acts as a reservoir from which bacteria can translocate to colonize pancreatic necrosis and acute fluid collections, resulting in infected pancreatic necrosis and pancreatic abscesses. Experimental studies appear to support this theory. Transient bacterial colonization of proximal small bowel occurs in a rat bile duct ligation model of acute pancreatitis and results in increased rates of bacterial translocation[14,15]. Furthermore, Widdison[16] in a series of experiments with a feline model of acute pancreatitis demonstrated that bacteria are able to reach the pancreas from the colon by direct transmural spread.

Table 1 Organisms associated with secondary infection in acute pancreatitis

Reference	Year	Nature	Mono	Poly	*Escherichia coli*	*Pseudomonas*	Other coliforms	*Staphylococcus*	*Enterococcus*	Fungus	Anaerobes
Miller *et al.*[10]	1974	Pancreatic abscess	57	43	36	13	55	15	21	—	—
Beger *et al.*[11]	1986	Infected necrosis	—	—	53	11	56	11	13	7	11

Fedorak *et al.*[7]	1992	Pancreatic abscess	40	60	30	20	80	30	40	5	15
Fedorak *et al.*[7]	1992	Infected pseudocyst	78	22	35	0	26	17	13	9	4
Bradley[8]	1993	Infected necrosis	66	34	47	10	34	2	3	6	—
Banks *et al.*[12]	1995	Pancreatic infection	—	—	23	4	37	25	14	4	4

Values are percentages of cases with each organism. Infective complications are classified using Atlanta consensus conference terminology[9]. Mono, Monomicrobial infection; Poly, polymicrobial infection

Translocation may also be important in the pathogenesis of the organ dysfunction that can complicate acute pancreatitis. Endotoxin, a lipopolysaccharide derived from the outer membrane of Gram-negative bacteria and a potent activator of inflammation, can be detected in the serum of patients with severe acute pancreatitis[17] and its presence is related to organ failure[18]. Windsor and colleagues[19] found that depletion, or significant falls in levels, of serum antiendotoxin immunoglobulin G antibody, believed to be secondary to exposure to endotoxin, correlated with the development of multiple organ failure in acute pancreatitis.

Penetration of antibiotics into human pancreatic tissue

Roberts and Williams[20] investigated the penetration of ampicillin into pancreatic tissue by sampling pancreatic ductal fluid at endoscopic retrograde cholangiopancreatography in ten patients given a loading dose of parenteral ampicillin. In six of seven subjects ampicillin was undetectable in the fluid. This indirect evidence of poor penetration of ampicillin into pancreatic tissue is lent further credence by the work of Trudel *et al.*[21], which demonstrated that ampicillin does not achieve bactericidal concentrations in pancreatic tissue in a canine model of acute pancreatitis.

Buchler and co-workers[22] compared human pancreatic tissue concentrations of ten bactericidal antibiotics administered intravenously in 89 patients undergoing pancreatic surgery to determine probable antibiotic efficacy in pancreatic infection. Antibiotic efficacy was estimated with reference to the antibiotic tissue concentration attained and the effect of that tissue concentration upon the types of organisms commonly involved in pancreatic infection. On this basis the antibiotics were divided into three groups. Group A consisted of the aminoglycosides, which failed to reach the minimum inhibitory concentration (MIC). Group B antibiotics reached tissue concentrations that were effective against some but not all organisms and included the extended-spectrum penicillins, mezlocillin and piperacillin, and the third generation cephalosporins, ceftizoxime and cefotaxime. Group C antibiotics consisted of the 4-quinolones and imipenem which reached tissue concentrations that were bactericidal for most infecting organisms. However, only eight of the samples were obtained from patients with acute pancreatitis and it is possible that patterns of antibiotic penetration in inflamed human pancreas are different.

Foitzik and colleagues[23] have demonstrated, in a rat model of acute pancreatitis, that pancreatic capillary blood flow and pancreatic oedema have marked effects on the pancreatic tissue concentration of parenterally administered cefotaxime, but not on pancreatic tissue concentrations of imipenem. Koch and colleagues[24] confirmed in a study of ofloxacin that the 4-quinolone class of antibiotics achieves bactericidal levels in normal pancreas, inflamed pancreatic tissue and pancreatic necrosis. Similarly, confirming that the third generation cephalosporins have good pancreatic penetration, Drewelow and colleagues[25] found that ceftazidime achieved antimicrobial tissue concentrations in both viable and necrotic pancreatic tissue in three human patients with acute necrotizing pancreatitis.

Bassi and co-workers[26] examined the penetration of aminoglycosides, perfloxacin, imipenem, mezlocillin and metronidazole into microbiologically proven infected pancreatic necrosis in humans. Following parenteral administration of antibiotics, pancreatic tissue samples were collected at the time of pancreatic necrosectomy or by computed tomography (CT)-guided needle aspiration. Although all of the antibiotics could be detected in necrotic tissue, only perfloxacin and metronidazole consistently attained levels greater than the MIC for organisms found in pancreatic infection. Mezlocillin and imipenem inconsistently attained levels greater than the MIC, although tissue concentrations of imipenem were increased by repeated administration. Aminoglycoside levels were always inadequate.

In summary, it appears that the third generation cephalosporins, piperacillin, mezlocillin, 4-quinolones, imipenem and metronidazole achieve useful pancreatic tissue concentrations, while the aminopenicillins, first generation cephalosporins and the aminoglycosides do not. However complex pathophysiological mechanisms may exist in the inflamed pancreas altering the pharmacokinetics of antibiotics.

Experimental evidence for antibiotic therapy in severe acute pancreatitis

The potential benefits of prophylactic antibiotics in the prevention of pancreatic infection complicating acute pancreatitis have been demonstrated in experimental studies. Foitzik and colleagues[27] studied the effects of intravenous and oral antibiotics in a rat model of severe acute pancreatitis induced by a combination of low-dose intraductal infusion of glycodeoxycholic acid superimposed on intravenous caerulein hyperstimulation. At 6 h, animals were randomly allocated into five treatment groups: controls, intravenous cefotaxime, intravenous imipenem, oral antibiotics (polymyxin E, tobramycin and amphotericin) and full gut decontamination (oral antibiotics plus intravenous cefotaxime). No treatment regimen affected the mortality rate at 96 h. At this time point, surviving animals were sacrificed for quantitative bacterial studies of the caecum, pancreas and kidney. Pancreatic bacterial counts were reduced by the intravenous imipenem and full-gut decontamination regimens but not by oral antibiotics or intravenous cefotaxime alone. Interestingly, although intravenous cefotaxime reduced rates of pancreatic infection by *E. coli*, this was compensated for by a rise in enterococcal infection. The failure to demonstrate a survival benefit from the prevention of pancreatic infection following intravenous imipenem or full-gut decontamination probably reflects the short follow-up, with early deaths arising from the primary physiological insult of acute pancreatitis rather than the effects of secondary pancreatic infection.

Similarly, in a feline model of pancreatic infection, Widdison and colleagues[28] demonstrated that intravenous antibiotics were efficacious in the elimination of pancreatic bacterial colonization in acute pancreatitis. Following induction of acute pancreatitis by ductal infusion of glycodeoxycholic acid, *E. coli* placed in the main pancreatic duct resulted in early bacterial colonization. This colonization persisted in animals at 1 week but could be eliminated completely by the use of intravenous cefotaxime started 12 h after the induction of pancreatic infection. No deaths were observed in any study group.

In further experiments with the rat intraductal infusion/caerulein hyperstimulation model of acute pancreatitis, the benefits of intravenous antibiotics over a prolonged period were studied[29]. Following induction of acute pancreatitis, animals were randomized to three groups: control, intravenous ciprofloxacin and intravenous imipenem. Antibiotics were commenced 12 h after the induction of pancreatitis. Disease severity was similar in the three groups as assessed by serum trypsinogen activation peptide assay. At 7 days 75 per cent of rats not receiving antibiotics had pancreatic infection with organisms similar to those found in humans. Imipenem and ciprofloxacin significantly reduced the rates of infection, bacterial counts and number of organisms cultured compared with those in controls. At 21 days, bacterial pancreatic colonization was present in 75 per cent of surviving control animals; although only 35 per cent of animals treated with antibiotics had bacterial colonization, the difference did not reach significance because of the low numbers of surviving animals. There was, however, a significant reduction in the rate of pancreatic abscess formation in antibiotic-treated animals. Most importantly, ciprofloxacin significantly reduced both the 7- and 21-day mortality rates, while imipenem significantly reduced the 21-day mortality rate.

Araida and co-workers[30] demonstrated, in a rat model of acute pancreatitis induced by ductal infusion of meglumine diatrizoate, lipopolysaccharide, taurocholic acid and enterokinase, that the administration of intravenous piperacillin was associated with a significant reduction in incidence of pancreatic infection and 24-h mortality rate.

Controlled clinical studies of antibiotic prophylaxis in severe acute pancreatitis

The use of prophylactic antibiotic therapy in acute pancreatitis is based on the rationale that the prevention of pancreatic infection will result in a reduction in morbidity and mortality rates. However, initial studies of antibiotic prophylaxis in acute pancreatitis were unable to demonstrate a difference in outcome between antibiotic-treated and control groups[31–33]. The failure of early trials to show any benefit was probably due not to a false hypothesis but rather to the use of ampicillin, a drug which is now known not to penetrate pancreatic tissue. Furthermore, these studies did not restrict entry to patients with prognostically severe acute pancreatitis. It is probable that the inclusion of patients with mild disease, who rarely develop pancreatic infection and improve regardless of intervention, reduced the ability of these studies to detect any potential benefit from treatment.

The issue of prophylactic antibiotics was re-addressed in 1993 by Pederzoli and colleagues[1] in a multicentre randomized controlled trial. Seventy-four patients with acute pancreatitis, all prognostically severe by Ranson's criteria[34] and with pancreatic necrosis proven by CT, were randomized to receive either imipenem 0·5 g intravenously at intervals of 8 h for 14 days or to a control group receiving no initial antibiotic therapy. Pancreatic infection was confirmed by positive bacterial cultures obtained by radiologically guided fine-needle aspiration or at operation. Of the control group, ten of 33 developed pancreatic infection, with the risk of developing such infection correlating strongly with the degree of pancreatic necrosis determined by CT. In comparison, despite having a greater degree of pancreatic necrosis, only five of 41 patients treated with imipenem developed pancreatic infection ($P < 0·001$). Furthermore, rates of non-pancreatic infection were also significantly reduced in the antibiotic-treated group. However, antibiotic therapy had no effect on the development of multiple organ failure, the need for operative intervention or on the mortality rate.

Sainio and colleagues[2], in a randomized control trial, studied the use of intravenous cefuroxime in patients with alcohol-induced acute pancreatitis and pancreatic necrosis proven by CT. Sixty patients were randomized either to a group receiving intravenous cefuroxime 1·5 g three times a day from admission until clinical recovery and normalization of serum C-reactive protein concentrations, or to a group in whom antibiotics were commenced only when there was clinical evidence of infection; no significant difference was found in the rate of pancreatic infection between the two groups (nine of 30 *versus* 12 of

30 respectively). However, intravenous cefuroxime appeared significantly to reduce the mean number of infectious complications per patient (1·0 *versus* 1·8 respectively, $P<0·01$), although this appeared to be due mainly to a marked fall in the number of urinary tract infections. Intravenous cefuroxime reduced the requirement for operative intervention (8 *versus* 36 operations respectively, $P=0·012$). Most importantly, there was a significant reduction in the number of deaths in patients treated with cefuroxime (one *versus* seven, $P=0·028$).

Recently, Delcenserie and colleagues[3] randomized 23 patients with alcohol-induced severe acute pancreatitis to either standard medical therapy or standard medical therapy plus intravenous ceftazidime, amikacin and metronidazole. Antibiotic therapy resulted in a significant reduction in the number of patients with proven infection (none *versus* seven, $P<0·03$); there was no significant reduction in the mortality rate. Although this study appears to show a benefit from the use of prophylactic antibiotics, the conclusions to be drawn must be limited because the size of the study sample was small and amikacin, an aminoglycoside, is from a class of drugs that do not penetrate the pancreas.

Following a small randomized controlled trial of 26 patients with pancreatic necrosis proven on CT, Schwarz and colleagues[35] have reported that the combination of ofloxacin and metronidazole administered intravenously lessens the physiological disturbance found in severe acute pancreatitis, but it neither prevented nor delayed the onset of infected pancreatic necrosis.

Interpretation of the message from these four studies requires caution. Reduced mortality rate did not consistently arise from a reduction in pancreatic infection. However, three of the trials did demonstrate a reduction in the rate of pancreatic infection following antibiotic therapy, although this reached statistical significance in only two. These inconsistencies may be a consequence of the relatively small number of patients enrolled in each trial reducing the power of the studies to detect significant differences. As different antibiotic protocols and inclusion criteria were involved, it would be inappropriate to carry out a meta-analysis. If a prospective study of sufficient sample power were to be performed, it would be expected that any demonstrable reduction in the incidence of pancreatic infection with treatment would be associated with a reduced requirement for surgical intervention. This in turn might be expected to translate into a reduction in overall mortality rate.

Choice of antibiotic

Ideally, the choice of antibiotic regimen should be determined by clinical trials. However, in the knowledge that antibiotic therapy is generally beneficial in severe acute pancreatitis and given the absence of direct comparisons between antibiotics, a pragmatic approach must be adopted. Several factors are important in choosing a prophylactic antibiotic, including adequate antibiotic tissue penetration, effectiveness against commonly involved organisms, cost-effectiveness and low incidence of adverse reactions. The important organisms involved in pancreatic infection include coliforms, enterococci, staphylococci and anaerobic bacteria, while the antibiotics that achieve adequate pancreatic tissue levels are the third generation cephalosporins, piperacillin, 4-quinolones, imipenem and metronidazole.

Third generation cephalosporins have a wide spectrum of activity against Gram-negative and Gram-positive organisms. Although different drugs in this category are generally active against similar organisms, some important differences exist, for example cefotaxime and ceftriaxone are less effective than ceftazidime against *Pseudomonas* spp. The third generation cephalosporins are active against staphylococci, albeit to a lesser extent than cefuroxime, a second generation cephalosporin. Interestingly, the pharmacokinetics of cefuroxime relating to pancreatic tissue are unknown and its failure to reduce rates of pancreatic infection in Sainio's study may indicate that pancreatic penetration is poor. Ceftriaxone should probably be avoided because it can form an insoluble salt in bile leading to biliary sludging. This sludging may induce acute pancreatitis[36].

The 4-quinolones (ciprofloxacin and ofloxacin) have high levels of activity against Gram-negative bacteria, including *Pseudomonas* spp., but only moderate activity against Gram-positive bacteria, with a high incidence of resistance among staphylococci. Susceptibility is low amongst anaerobic bacteria. However, the high cost of intravenous ciprofloxacin does not favour its use as routine prophylaxis.

Metronidazole combines anaerobic activity with good penetration into pancreatic tissue[22,26,37]. Although there have been isolated reports of metronidazole-induced acute pancreatitis[38,39], a large retrospective study of prescribed metronidazole found no increased risk from its use[40].

The acylureidopenicillins, piperacillin and mezlocillin, have wide spectrums of activity, including action against *Pseudomonas* spp., *Enterococcus* spp. and anaerobes. Addition of the β-lactamase inhibitor tazobactam increased the spectrum of activity of piperacillin. Again cost considerations restrict the use of intravenous piperacillin/tazobactam.

The carbapenem group of antibiotics, including imipenem, has a very broad spectrum including activity against *Pseudomonas* spp., *Staphylococcus* spp. and *Enterococcus* spp. and achieves good penetration into pancreatic tissue[22,26]. As resistance to this group remains uncommon, the use of its component drugs is at present confined to second-line therapy in serious infection. This, together with the high cost of therapy, makes routine use of this drug grouping as prophylaxis inappropriate.

Prophylaxis against infection by *Enterococcus* spp. is problematic. Not only is antibiotic resistance in enterococci becoming increasingly common[41,42], the current therapeutic regimen of choice, ampicillin alone or in combination with gentamicin, employs antibiotics with poor penetration into pancreatic tissue, while the second-line chemotherapeutic agent vancomycin has potentially serious side-effects and no data exist regarding its penetration into the pancreas. Piperacillin and imipenem have useful activity against *Enterococcus* spp. Prophylaxis against *S. epidermidis* is similarly complicated. *Staphylococcus epidermidis* is often sensitive to cephalosporins, but unpredictable multidrug resistance occurs[43].

Alternative strategies: selective decontamination of the gut

Intravenous antibiotic prophylaxis in acute pancreatitis is based on the belief that adequate pancreatic tissue levels of antibiotics can prevent colonization of the inflamed pancreas following translocation of organisms from the gut. Selective gut decontamination with oral antibiotics is an alternative strategy, aimed at eliminating pathogenic intestinal flora to reduce bacterial translocation, thereby reducing the risk of pancreatic infection.

As previously discussed, Foitzik and co-workers[27] demonstrated that oral antibiotics alter normal intestinal flora and, when combined with intravenous antibiotics, lead to a reduction in the rate of pancreatic infection. Similarly, in a mouse model of severe acute pancreatitis induced by a choline-deficient diet supplemented with 0·5 per cent DL-ethionine Isaji and colleagues[44] demonstrated that therapy with oral bacitracin, metronidazole and neomycin antibiotics resulted in reduced rates of positive bacterial cultures from samples of peripheral blood, ascites, spleen and pancreas, and significantly improved survival. Interestingly, Gianotti and colleagues[45] have evaluated several different gut decontamination regimens in a mouse model of acute pancreatitis. Although all decontamination regimens resulted in significant reductions in bacterial flora, not all were associated with decreased rates of bacterial translocation and reduced mortality rates, suggesting that the benefits of gut decontamination do not arise solely from the elimination of pathogenic intestinal bacteria.

Luiten and colleagues[46] evaluated the role of selective gut decontamination in patients with severe acute pancreatitis. In a multicentre trial, 102 patients with prognostically severe acute pancreatitis as defined by multiple laboratory criteria (Blamey and colleagues[47]) and/or contrast-enhanced CT scoring (Balthazar *et al.*[48]) were randomized to either conventional therapy or conventional therapy supplemented with selective gut decontamination using oral and rectal colistin, amphotericin and norfloxacin. In addition, patients in the selective gut decontamination group received intravenous cefotaxime until aerobic Gram-negative bacteria were eliminated from the oral cavity and rectum. Although there was a reduction in mortality rate from 35 per cent in the control group to 22 per cent in the group given selective decontamination, this did not reach statistical significance. However, when allowing for differences in disease severity, multivariate analysis suggested a significant survival benefit following gut decontamination ($P = 0{\cdot}048$). Encouragingly, selective gut decontamination reduced the rate of pancreatic infection compared with that of the control group (38 *versus* 18 per cent, $P = 0{\cdot}03$).

Discussion

Infected pancreatic necrosis and pancreatic abscess remain feared complications of severe acute pancreatitis because of the attendant increase in the risk of death and the requirement for surgical intervention[11]. Despite improvements in intensive care medicine and surgical practice, the problem continues[49]. Early attempts at preventing the development of pancreatic infection by using antibiotic prophylaxis foundered because of improper patient selection and inappropriate antibiotic usage. However, based on improved knowledge of the pathogenetic mechanisms of the disease and better understanding of antibiotic pharmacokinetics, recent clinical trials have demonstrated a benefit from antibiotic prophylaxis in severe acute pancreatitis[50]. Unfortunately, doubts about its effectiveness persist. The recent American College of Gastroenterology practice guidelines[51] merely state that it is 'reasonable to initiate' antibiotic therapy in severe acute pancreatitis, while Barie[4] in his review is more critical of the present evidence.

Following consideration of the organisms implicated in pancreatic infection, the evidence upon which the merit of prophylactic antibiotics in acute pancreatitis must be judged has been reviewed. It is concluded that, in contrast to Barie's statement, there is experimental and clinical evidence to suggest that current practice in patients with severe acute pancreatitis should incorporate prophylactic antibiotic therapy. However, the weight of this evidence is reduced by the fact that the four small prospective clinical studies available have not shown a consistent reduction in pancreatic infection. There is, to date, no large-scale prospective study of sufficient sample power to make the use of antibiotic prophylaxis mandatory.

The authors agree with Johnson[50] that therapeutic issues remain, particularly in determination of the ideal antibiotic and the duration of therapy. However, appropriate studies to define these variables may be difficult to undertake. Assuming 30 per cent of patients with prognostically severe acute pancreatitis develop infected pancreatic necrosis, a total sample size of 322 is required to detect a 50 per cent reduction, assuming a two-tailed test with significance level of 5 per cent and a study power of 90 per cent. Even larger studies would be required to evaluate reductions in mortality rate. Furthermore, the stage of clinical equipoise between prophylactic antibiotic therapy and no antimicrobial therapy has almost certainly passed; clinicians may be reluctant to enter patients with severe acute pancreatitis into studies involving a 'no antibiotic' arm. Although less than satisfactory, further evidence may have to derive from observational studies. Ho and Frey[52] have recently published a retrospective study suggesting a reduction in the rate of pancreatic infection, in patients with prognostically severe acute pancreatitis admitted to their institution, following the introduction of a policy of prophylactic administration of intravenous imipenem for 4 weeks.

In summary, although the rationale for continuing investigation of the value of antibiotic therapy in severe acute pancreatitis is clear, Barie's[4] notion that more studies of this therapeutic modality are required to address the 'myriad issues yet to be resolved' is impractical. In a common and often fatal disease such as acute pancreatitis, where there is a paucity of rational therapeutic interventions, the loss of a potentially valuable therapy such as antibiotic prophylaxis would be unfortunate.

Review

Diagnosis and treatment of sphincter of Oddi dysfunction

G. TZOVARAS and B. J. ROWLANDS

Department of Surgery, The Queen's University of Belfast, Belfast, UK

Background Sphincter of Oddi dysfunction is a challenge from both the diagnostic and therapeutic point of view. There is much ongoing debate about the accuracy and usefulness of various diagnostic tests, as there is about the effectiveness of proposed therapeutic alternatives.

Methods A comprehensive review of the past 15 years' literature was undertaken, using the Medline database and cross-referencing of major articles on the subject.

Results and conclusion Endoscopic and surgical treatments result in similar outcomes, with considerable failure rates. The latter reflect the difficulties in accurate diagnosis and a lack of sound objective criteria for selecting patients for intervention. In addition, in some patients sphincter of Oddi dysfunction may be only part of a generalized motility disorder of the gastrointestinal tract.

The sphincter of Oddi is a complex muscular structure consisting of smooth muscle fibres that surround the distal common bile duct (CBD), pancreatic duct and ampulla of Vater (the common channel of both ducts)[1–3]. It is 6–10 mm in length and is situated almost entirely in the wall of the duodenum, traversing it obliquely[4,5]. It is composed of small muscular segments, described by Boyden[4] in a detailed study: the sphincter choledochus (which surrounds the distal CBD), the sphincter pancreaticus (which surrounds the lower end of the pancreatic duct) and the sphincter ampullae (which surrounds the common channel or ampulla). The most important element seems to be the sphincter choledochus; the sphincter pancreaticus is identified in only 10 per cent of specimens[4].

This group of smooth muscle fibres is functionally independent of duodenal muscle and its primary function is to control the delivery of bile and pancreatic juice into the duodenum. This sphincter also diverts bile into the gallbladder and prevents retrograde reflux of duodenal luminal fluid into the ducts[1]. Bile flow occurs mainly by a passive mechanism between phasic contractions, the contractions serving to propel a small bolus of fluid to clear the ductal opening[5]. Understanding of sphincter of Oddi function relied initially on information obtained from the intraoperative measurement of CBD duct pressure and flow of contrast agent through the papilla using a debimanometer, as described by Tondelli and Gyr[6]. Subsequent use of endoscopic manometry has enhanced understanding of both normal and abnormal sphincter function. Today, the sphincter of Oddi is believed to be a more dynamic structure than it was thought to be in the past. Sphincter motility differs in fasting, when it is integrated with the migrating motor complex (MMC), and the postprandial state, when the control mechanisms of motility are unclear.

The MMC pattern of gastrointestinal motility during fasting propagates from the distal oesophagus[7,8] to the ileum periodically every 90–120 min and is divided into four phases. Bile flow into the duodenum during fasting occurs in a cyclical pattern in concert with the MMC phases, to reach a maximum during the latter portion of the MMC[9]. The frequency of myoelectrical spike potentials of the sphincter of Oddi increases gradually from phase I to a maximum in phase III and then decreases rapidly during phase IV. This may represent a preventive mechanism against accumulation of biliary microcrystals and debris, and the creation of calculi, during fasting.

After food the pattern of gastrointestinal motility changes and the sphincter of Oddi mirrors these changes by irregular bursts of spike potentials. The frequency of spike potentials depends on the type and amount of food ingested, fat and proteins causing the greatest frequency of sphincteric activity[9].

What is dysfunction of the sphincter of Oddi?

Many articles have been published in the past two decades about the clinical syndrome described as 'dysfunction of the sphincter of Oddi'. Such dysfunction could affect the biliary duct leading to pain characteristic of biliary colic, or the pancreatic duct causing recurrent acute pancreatitis. The clinical syndrome is poorly defined, incompletely understood and difficult to diagnose. A number of terms have been used to describe the same clinical entity (e.g. papillary stenosis, sclerosing papillitis, biliary spasms, biliary dyskinesia, postcholecystectomy syndrome) which has resulted in some confusion. Recently, to avoid such confusion, two types of sphincter of Oddi dysfunction have been proposed on the basis of pathogenic mechanism[10,11].

Sphincter of Oddi stenosis

Sphincter of Oddi stenosis is a structural abnormality in which there is narrowing of part or all of the sphincter due to chronic inflammation and fibrosis. It is associated with pancreatitis or injury from gallstone migration through the papilla, trauma from intraoperative manipulation of the CBD or non-specific inflammatory conditions, such as adenomyosis. This structural abnormality is further associated with raised basal sphincter pressure and alteration of phasic contractions measured by endoscopic manometry.

Sphincter of Oddi dyskinesia

Sphincter of Oddi dyskinesia is an intermittent functional blockage of the high-pressure zone of the sphincter. It

Paper accepted 12 January 1998

results from spasm, hypertrophy or denervation of the sphincter muscle. This condition may reflect a motility disorder of the sphincter similar to motility disorders elsewhere in the gastrointestinal tract (e.g. hypertensive lower oesophageal sphincter). Basal pressure is raised but, unlike in structural stenosis, it may be reduced by the administration of smooth muscle relaxants (nitrates). However, there is still a significant overlap in the manometric values found in both types of sphincter of Oddi dysfunction.

Diagnosis of sphincter of Oddi dysfunction

Sphincter of Oddi dysfunction should be suspected in patients with pain of apparent biliary or pancreatic origin, in the absence of an organic cause (after conventional investigations). Twenty-nine per cent of patients with unexplained right upper quadrant abdominal pain who have a normal extrahepatobiliary and pancreatic system have manometric evidence of sphincter of Oddi dysfunction[12]. It is difficult to assess accurately the incidence in the general population. In many cases the diagnosis is somewhat arbitrary and difficult to prove, but it is estimated that it occurs in 0·88 per cent of those undergoing cholecystectomy[13]. Cholecystectomy may reveal previously unrecognized pre-existing symptoms due to sphincter of Oddi dysfunction because there is no longer a gallbladder to serve as a reservoir to accommodate pressure and volumetric changes[14]. However, there is little doubt that in most cases symptoms after cholecystectomy are non-biliary in origin[15]. The true incidence of sphincter of Oddi dysfunction as a cause of recurrent acute or chronic pancreatitis is impossible to estimate, but an association exists between sphincter dysfunction and pancreatic disease. Abnormal manometric findings in patients with early minimal-change chronic pancreatitis have been reported recently[16] and, when other common causes of pancreatitis have been excluded, sphincter dysfunction should be considered in the differential diagnosis. Numerous tests have been proposed to obtain an accurate diagnosis, but they are insensitive and non-specific.

Hogan and Geenen[17] have suggested a classification for suspected sphincter of Oddi dysfunction known as the Milwaukee Biliary Group Classification (*Table 1*). This seeks to outline an optimal scheme for investigation and to predict the outcome of endoscopic sphincterotomy or surgical sphincteroplasty. Sherman *et al.*[18] have described a similar classification for pancreatic type pain (*Table 2*).

After cholecystectomy, a dilated CBD detected by ultrasonography has been proposed as a feature of sphincter of Oddi dysfunction[19] which has high predictive value for favourable outcome after sphincterotomy[20]. However, it is a non-specific feature which can be detected in 4 per cent of asymptomatic patients after cholecystectomy[21,22]. In addition, the diameter of the CBD varies with the age of the patient[9]. Determination of the increase in duct diameter after a fatty meal or cholecystokinin octapeptide may be useful in the evaluation of the function of the sphincter of Oddi[23,24]. No increase in diameter after provocation, measured by ultrasonography, should occur in normal subjects, because normal changes in sphincter motility should enhance bile flow into the duodenum and decrease the diameter of the CBD[11]. A paradoxical increase in CBD diameter reflects an abnormal resistance to bile outflow and an increase greater than 2 mm is observed in patients with sphincter dysfunction[23].

Table 1 Milwaukee Biliary Group Classification, after Hogan and Geenen[17]

	Biliary type pain	Abnormal liver function test results*	Dilated common bile duct†	Delayed drainage‡
Type I	+	+	+	+
Type II	+	One or two of the above		
Type III	+	None of the above		

*Alanine transaminase and aspartate transaminase levels more than two times normal value, on at least two occasions; †more than 12 mm on ultrasonography or 10 mm on endoscopic retrograde cholangiopancreatography; ‡more than 45 min on ERCP in the supine position

Table 2 Pancreatic type pain classification, after Sherman *et al.*[18]

	Recurrent pancreatitis and/or typical pancreatic pain	Abnormal enzymes*	Dilated pancreatic duct†	Delayed drainage‡
Type I	+	+	+	+
Type II	+	One or two of the above three		
Type III	+	None of the above three		

*More than 1·5–2 times the upper limit; †greater than 6 mm in the head and more than 5 mm in the body on endoscopic retrograde cholangiopancreatography; ‡more than 9 min

A similar ultrasonographic method has been proposed for the evaluation of the pancreatic component of the sphincter of Oddi. The diameter of the pancreatic duct in normal individuals measures less than 1 mm. Following secretin injection, there is a temporary increase in pancreatic duct diameter that lasts for less than 30 min. A diameter greater than 1·5 mm at 30 min suggests a resistance to the outflow of pancreatic juice[25]. This test is operator dependent for evaluation and interpretation but it is non-invasive, easy to apply and inexpensive. It is useful as a screening investigation and may alert the physician to the possibility of sphincter of Oddi dysfunction[11].

Another commonly used measure of sphincter dysfunction is delayed emptying of the CBD at endoscopic retrograde cholangiopancreatography (ERCP). ERCP is one of the first-line investigations of symptoms of hepatobiliary and pancreatic origin. It is an excellent test that gives the most accurate image of both biliary and pancreatic ducts. It is a useful tool to exclude CBD obstruction caused by stone or stricture, or to demonstrate a congenital abnormality, such as pancreas divisum[26]. Failure to cannulate either duct may raise suspicion that an anatomical deformity exists[26] but interpretation is subjective and operator dependent. Reproduction of pain during injection of contrast medium has not been generally accepted as a reliable indicator of sphincter dysfunction. The papilla may appear normal at ERCP or at the time of intraoperative inspection, despite the presence of marked fibrosis[26]. Delay in emptying of contrast medium for more than 45 min is consistent with sphincteric dysfunction[19,27] and has a high predictive value for favourable outcome after sphincterotomy[20]. The test is, however, poorly standardized, because during ERCP varying amounts of contrast agent may be injected into the biliary tree and differing amounts of sedative, potentially affecting sphincter motility, may be administered[2,10]. The invasive nature of ERCP and the use of sedation are the main disadvantages of the procedure.

Dynamic hepatobiliary scintigraphy has been used as a non-invasive tool for evaluation of the sphincter of Oddi by providing indirect evidence of increased sphincter resistance. This method can be standardized, and can give quantitative and qualitative information by measuring a significant delay in hepatic uptake and washout[2,28]. It has high sensitivity and should be used as an early diagnostic tool to evaluate suspected sphincter dysfunction[9] after a structural lesion of the CBD has been excluded[2]. The hilar time–activity curve and the 45-min clearance value are the most useful criteria for differentiating between partial biliary obstruction and normality[29]. Nevertheless, in a large proportion of patients with sphincter dysfunction it fails to detect any abnormality, and there is a considerable overlap with the normal population[14]. The test cannot differentiate parenchymal liver disease, intrahepatic cholestasis and extrahepatic bile duct pathology[2,9]. It is useful for providing information about the biliary component of the sphincter but it does not help in pancreatic pain. The episodic nature of the disorder, especially dyskinesia, means that abnormal scintigraphy is unusual when the procedure is performed in a patient who is currently free of pain[30]. This has led some to use scintigraphic techniques after stimulation with cholecystokinin, and a scoring system has been proposed which combines visual and quantitative criteria for the diagnosis of sphincter dysfunction[28]. Cholecystokinin has been used as a functional stimulus to accentuate differences in bile flow rates between a normal postcholecystectomy population and those with sphincter of Oddi dysfunction. The scoring system incorporates all the variables previously demonstrated to be of significance in the diagnosis of sphincter dysfunction: time of peak liver activity, time at which the intrahepatic biliary tree is first visualized, prominence or dilatation of the biliary tree, time at which the bowel is first visualized, percentage of CBD emptying and CBD:liver ratio. This score appeared to be superior to previous diagnostic criteria and attained a perfect separation between patients with sphincter of Oddi dysfunction and controls (sensitivity 100 per cent, specificity 100 per cent)[28].

A series of provocation tests has been used with equivocal results and debatable usefulness. The most widely known, using various methodologies, is the morphine–prostigmine provocation test (Nardi test)[31]. This test is performed by giving an intramuscular injection of morphine 10 mg and prostigmine 1 mg to produce simultaneously spasm of the sphincter of Oddi and stimulation of exocrine pancreatic secretion. Reproduction of the patient's pain and/or increase in pancreatic or liver-associated enzymes are required for a positive result. This test also identifies those who are most likely to benefit from sphincteroplasty and septectomy[31]. Abnormal responses to morphine–neostigmine in patients with undefined biliary pain have also been reported[32] and there is evidence that the test may be beneficial in chronic relapsing pancreatitis in children[33]. However, other studies have suggested that the method is neither specific nor sensitive for sphincter of Oddi dysfunction[34,35]. These discrepancies of information and interpretation might be due to different methodologies and the varying criteria of positivity used by different authors. The test is cheap and easy to perform but seems to have a low specificity when it is considered alone. It should be used as a screening test in patients with pain of hepatobiliary and pancreatic origin. A combination of scintigraphy and the provocation test has recently been used for postcholecystectomy syndrome[30]. The results were encouraging and showed a good correlation between a positive provocation test and an obstructive pattern on scintigraphy. This combination may be the optimal method for detection of the subgroup of patients with functional abnormality (dyskinesia), but larger studies are required to assess the diagnostic accuracy and predictive value of response to endoscopic or surgical therapy.

Recently there has been a surge of interest in manometry as a diagnostic tool. Three manometric methods have been described: direct endoscopic manometry, indirect manometry and tip transducer manometry[9]. Direct endoscopic manometry is considered the 'gold standard'. It is performed endoscopically through retrograde cannulation of the sphincter with a standard 1·7-mm triple-lumen, side-hole, manometry catheter. The catheter is perfused with distilled water at a low constant flow by a low-compliance perfusion system. The pressure is transmitted constantly through the catheter to external transducers, which transform it to an electrical signal that is amplified and recorded. Selective cannulation of both bile and pancreatic duct is important to evaluate both components of the sphincter, and to exclude any segmental dysfunction responsible for partial biliary obstruction or episodes of acute recurrent pancreatitis[36,37]. The basal pressure of the sphincter of Oddi is usually 5–15 mmHg greater than the pressure in the CBD and 15–30 mmHg greater than that in the duodenum, which is used as zero reference. Phasic contractions of amplitude 50–150 mmHg are superimposed on the basal pressure with a frequency varying between 3 and 8 contractions per min. Most are propagated in an antegrade fashion[9]. Manometric abnormalities ascribed to sphincter of Oddi dysfunction include high basal pressure (more than 40 mmHg), increased amplitude (more than 240 mmHg) or increased frequency (greater than 10 per min) of phasic contractions and increased percentage (more than 50 per cent of the time) of retrograde propagated contractions and paradoxical response to cholecystokinin[10,38–40]. Raised basal pressure appears to be the most consistent, reliable and frequently used variable for therapeutic decision making[3,40]. It has been shown by Geenen *et al.*[41] in a prospective trial that raised basal sphincter pressure is the most reliable finding to predict a successful outcome of endoscopic sphincterotomy. However, others have failed to correlate a favourable outcome with manometric assessment[20,42] and have emphasized that the presence of either a dilated duct or delayed drainage of contrast agent at ERCP predicts a favourable outcome following sphincterotomy[20]. Roberts-Thompson and Toouli[42] in a retrospective series reported good results after endoscopic sphincterotomy in five of eight patients with normal sphincter of Oddi manometry, while seven of 17 patients with abnormal manometric findings (suggesting either stenosis or dyskinesia of the sphincter) failed to have any change in symptoms. They concluded that the results of sphincterotomy appeared to be unrelated to manometric findings.

Several problems occur in the performance and interpretation of biliary manometry. First, the procedure itself is an expensive and sophisticated one, performed in only a few specialized centres. It is quite difficult to carry out, is invasive and requires sedation, which may modify the behaviour of the sphincter. Even an experienced endoscopist may achieve an adequate and complete examination in only 54–87 per cent of patients[13,15,38]. Meshkinpour and Mollot[43] found recently, in a series of 64 patients with postcholecystectomy syndrome, that only 41 per cent had a manometric abnormality. Furthermore, even among patients with type I disease in the Milwaukee classification (the most homogeneous and stringently selected group) 27 per cent had manometric values within the range recorded in healthy volunteers.

Endoscopic biliary manometry also has a higher incidence of associated pancreatitis compared with simple diagnostic ERCP. Approximately 2 per cent of 315 patients undergoing diagnostic ERCP developed pancreatitis compared with four of 21 patients undergoing sphincter manometry[44]. The incidence of postmanometry pancreatitis depends on the rate and time of catheter perfusion and whether the pancreatic segment of the sphincter is evaluated[45]. Sherman *et al.*[46,47] have reported a reduction of procedure-related pancreatitis from 31 to 4 per cent following evaluation of the pancreatic segment of the sphincter when one lumen of the triple-lumen catheter was used to aspirate the intraductal juice continuously; there was essentially no change in the recording pressure caused by this modification.

In addition to the above, other problems confound the interpretation of manometric findings. Very few investigators have studied normal volunteers and even those who have have produced very small series. More accurate conclusions could be drawn from manometric data collected from large numbers of asymptomatic individuals over a wide range of ages, from both men and women, with and without cholecystectomy, fed and fasted, and observed over a long period of time[40]. On the other hand, many patients suspected of having sphincter of Oddi dysfunction have postcholecystectomy pain and the effect of gallbladder removal on sphincter activity has not been determined. Thus an important control group that should be studied in more detail is that containing asymptomatic subjects after cholecystectomy[2]. The test itself may be problematic in that a relatively large tube is placed in a small opening, leading to obstruction of the biliary system, which is then perfused with water at low pressure[40]; the patient is sedated. For these reasons the procedure does not reproduce normal physiological conditions[40]. Methodological variations in catheters and infusion systems may account for differences in absolute pressure measurements between different laboratories. The problem of interobserver variability in the interpretation of manometry data has been addressed recently and significant disagreement was found in the reading of the absolute basal sphincter pressure and in the final diagnosis of normal *versus* abnormal[48]. However, in one study from a centre with a large experience of endoscopic manometry, when three experienced observers reviewed randomly selected manometric tracings, agreement was reached in a high proportion of cases in evaluation of normal *versus* abnormal baseline sphincter pressures[49].

Another question which is difficult to answer is whether or not the abnormalities noted on sphincter manometry correlate with pain, because the patient is sedated during the procedure. Furthermore, the assessment of sphincter activity obtained by manometry is limited to a brief period and this may be misleading in view of the intermittent nature of the disorder[40]. Tanaka *et al.*[50] overcame this problem by using the tip transducer technique in which an indwelling microtransducer catheter is placed into the CBD at the time of ERCP and remains there after removal of the endoscope and recovery of the patient. This method has the advantages of being more physiological and permitting the collection of information over a longer period. It also allows the evaluation of the effect of agents, such as morphine or smoking, on sphincter motility, and the correlation of intensity of pain with changes in sphincter pressure.

It is estimated that, if endoscopic manometry were employed to screen patients with postcholecystectomy pain, 7·2 studies would be performed for every case of sphincter of Oddi dysfunction detected[28]. This efficacy ratio is unacceptable for an invasive procedure that is both difficult to perform and associated with potentially dangerous complications. Biliary manometry is an important method of evaluation of sphincter of Oddi function, but at present it is more useful as a research tool than as a routine clinical investigation.

For indirect biliary manometry a catheter is inserted into the cystic duct or a T tube, fluid infusion is performed and pressures are obtained. Tondelli and Gyr[6], in 1983, described their debimanometer and proposed pressure-controlled cholangiography for intraoperative diagnosis of sphincter dysfunction. Their criteria for stenosis were residual pressure in the CBD of more than 16 cm contrast medium, standard flow through the papilla at a constant pressure of 30 cm contrast medium below 14 ml/min, and no normalization of these values after the administration of cholecystokinin. This method played an important role in understanding sphincter physiology using indirect methods that measured pressure in the CBD and flow through the sphincter, rather than direct measurement of the sphincter pressure. Other drawbacks, compared with endoscopic manometry, were that it could only be used during surgery and that it was both less physiological and less precise[9].

The ideal test to diagnose sphincter of Oddi dysfunction has yet to be identified, but endoscopic manometry is considered the best available by several authors, despite its obvious problems. In a recent prospective study[51], the Milwaukee Biliary Group Classification correlated well with clinical outcome after endoscopic sphincterotomy in 33 patients. Sphincterotomy was performed on the basis of raised basal pressure measured manometrically, but manometric findings did not correlate with either the Milwaukee classification or clinical outcome in patients with suspected sphincter of Oddi dysfunction type II (20 patients) or III (13). This poor correlation between the Milwaukee classification and manometric findings has been reported previously by others[52]. In another recent prospective series, which included patients with biliary type II and III disease, various preoperative tests were compared with respect to the results of sphincterotomy carried out on the basis of manometrically proven raised basal pressure in 23 patients[53]. A positive morphine–neostigmine test, pain induced by the injection of contrast agent at ERCP and delayed drainage of contrast from the CBD were associated with a favourable clinical outcome from endoscopic sphincterotomy in 18, 17 and 14 of the 23 patients respectively. These results were not significantly different from those of pathological sphincter of Oddi manometry, which was associated with a favourable outcome in 19 patients[53].

On balance, a single approach to the problem seems unjustified. Diagnosis and therapy should be based on a range of preoperative tests and clinical presentation. The

Milwaukee classification, which combines clinical, biochemical, ultrasonographic and ERCP findings, has a significant role to play in the assessment of suspected sphincter of Oddi dysfunction. This classification seems to predict the outcome of a sphincter ablation procedure accurately[51]. Intervention is justified in patients with type I disease, the vast majority of whom will experience benefit from sphincter ablation. In type II, the indication for any intervention is questionable; in type III, surgical or endoscopic intervention may create more problems than it solves. Manometry is not necessary for type I, as most patients have a uniformly abnormal basal pressure. In type II, it may provide useful information and identify a subgroup that may benefit from treatment. Most patients with type III disease have normal pressures so that manometry is redundant. If manometry is normal or not available, a diagnosis and a decision about intervention may be based on the rigorous application of available diagnostic tests.

Treatment

Sphincter of Oddi dysfunction is uncommon and is not life-threatening, but patients who suffer from it are severely debilitated. To make a diagnosis of sphincter of Oddi dysfunction and accurately select patients for treatment is difficult. When selection is based on strict criteria, the result may still be poor. An explanation for this is that sphincter dysfunction, particularly in dyskinesia, may represent part of a generalized gastrointestinal motility disorder. Treatment directed to one part of the gastrointestinal tract in such circumstances cannot be expected to improve or cure all symptoms[5,54].

The objective of treating sphincter of Oddi dysfunction is to facilitate drainage of biliary and pancreatic secretion into the duodenum. Three methods have been described which may achieve this goal: pharmacological treatment, endoscopic treatment (sphincterotomy and/or stenting) and surgical treatment (sphincteroplasty and biliary–enteric drainage). The endoscopic and surgical approaches are the most widely used.

The pharmacological approach has been proposed as a reasonable initial step, especially for functional dyskinesia[55]. Indeed, there is increasing interest in evaluating smooth muscle relaxants, such as nitrates or calcium channel blockers, based on the theory that the pain of sphincter of Oddi dysfunction is probably due to constriction of the sphincter and dilatation of the ducts proximal to the obstruction[2]. Bar-Meir *et al.*[56] reported a single case of nitroglycerine improving the pain of a patient with suspected sphincter dysfunction, with relaxation of the sphincter measured endoscopically. A therapeutic role for nifedipine was suggested by Laslo and Sandor[57], who reported an excellent clinical response from nifedipine therapy in four, a good response in seven and poor response in three of 14 patients with sphincter of Oddi dysfunction. Guelrud *et al.*[58] showed that nifedipine affects sphincter motor activity in both normal volunteers and patients with dysfunction by decreasing the basal pressure. Intolerable side-effects, however, limit the usefulness of these agents[58]. Recently Khuroo *et al.*[55], in a prospective double-blind randomized trial of 28 patients with dysfunction, showed that oral nifedipine at the maximum tolerated dose relieved pain in 21, principally in those with raised basal pressure and predominantly antegrade sphincter of Oddi contractions. The authors recommend that a trial of calcium channel blockers or long-acting nitrates is justified in biliary dyskinesia, retaining the other treatment modalities for those who fail to respond.

Some investigators have proposed stenting of the sphincter of Oddi as a minimally invasive method of treatment. In a recent study, stenting was used in patients with suspected sphincter dysfunction but no increase in basal sphincter pressure, on the assumption that these patients might have intermittent spasm[59]. There was a poor symptomatic response associated with a high risk of stent-induced pancreatitis, suggesting that stenting cannot be recommended as a routine method of treatment.

It is impossible to answer definitively the question of whether or not endoscopic sphincterotomy is better than surgical sphincteroplasty; no randomized trial comparing these two treatments has been carried out and the results from either retrospective or prospective trials of either option contain inherent bias. Furthermore, the heterogeneous patient populations and the different selection criteria used in different series make results difficult to compare in any meaningful way. The results of both surgical and endoscopic series published in the past 15 years are presented in *Tables 3* and *4*. Poor results are common with both endoscopic sphincterotomy (13–39 per cent) and surgical sphincteroplasty (7–35 per cent). This probably reflects the lack of specific objective tests to diagnose the disorder accurately and to select patients for intervention.

As endoscopists have become more adept at sphincterotomy, treatment seems to have shifted from surgical to endoscopic methods[71]; still, there is no evidence in the literature to suggest superiority over surgical sphincteroplasty. According to some authorities[71], treatment should be modified depending on co-existing medical illness, secondary hepatic dysfunction, the degree of pain, periampullary anatomy, and the type and degree of sphincter dysmotility. In an important prospective study

Table 3 Results of surgical treatment

*National study, collective data from 25 German centres; †prospective randomized trial, type II Milwaukee classification, sphincterotomy ($n = 23$) *versus* sham ($n = 24$); ‡prospective trial, type II and III Milwaukee classification, manometric criteria for sphincterotomy

by Geenen *et al.*[41], 47 patients with biliary-like pain (type II) were randomized to endoscopic sphincterotomy (23 patients) or sham procedure (24). Manometry was carried out, but not used as a criterion to determine therapy, and the manometric findings were correlated with the clinical outcome. After a 4-year follow-up, 17 of 18 patients with abnormal basal pressure (greater than 40 mmHg) had an improvement in their symptoms after sphincterotomy, compared with one of five after a sham procedure. Among those with normal basal pressure (less than 40 mmHg) only five of 12 had an improvement after sphincterotomy, compared with four of 12 after the sham procedure. In this study sphincterotomy did not afford any therapeutic benefit beyond its placebo effect when the sphincter pressure was normal, in patients with type II disorder.

Endoscopic sphincterotomy performed for papillary stenosis may be associated with a higher morbidity rate than sphincterotomy for calculi[70,72,73]. Patients undergoing endoscopic sphincterotomy for papillary stenosis are five times more likely to develop restenosis at the sphincterotomy site than those who have endoscopic sphincterotomy for calculi[70]. Riemann *et al.*[69] described recurrent stenosis in two of six patients subjected to endoscopic sphincterotomy for papillary stenosis, and Bozkurt *et al.*[53] needed to repeat sphincterotomy in three of 23 patients because of restenosis. In a multicentre study (German National Survey) of long-term results after endoscopic sphincterotomy for papillary stenosis, recurrent stenosis, defined by radiological findings, occurred in 12 per cent of 96 patients[70]. Isolated cases of relapsing pancreatitis after endoscopic sphincterotomy have been reported and have been attributed to subsequent scarring and progressive narrowing of the pancreatic duct orifice[74].

Transduodenal sphincteroplasty with transampullary septectomy (TDS-TAS) has been well standardized over the past two decades and is designed to provide adequate drainage of both bile and pancreatic juice from their respective ducts. Originally, the procedure included division of the entire length of the sphincter of Oddi, with suturing of the mucosa of the bile duct to the duodenal mucosa to prevent narrowing of the opening and extravasation of biliopancreatic secretion[75]. Later, involvement of the transampullary septum in the inflammatory and fibrotic process with subsequent obstruction of the pancreatic outflow was demonstrated by some authorities, who proposed the addition of septectomy to the original operation[31,60]. The same procedure carried out using a carbon dioxide laser has been proposed as a more rapid, accurate and safe method, with less haemorrhage and no greater complication rate than the classical surgical procedure[76].

There are two theoretical advantages of the surgical procedure over endoscopic sphincterotomy. First, endoscopic sphincterotomy does not affect the transampullary septum and drainage of pancreatic duct, although there are occasional reports of endoscopic septotomy[77,78]. The transampullary septum is considered to play a primary role in the pathological process because of the muscular interrelationships of the fibres of the sphincter. This thin veil of tissue is so strategically placed that, when thickened by inflammation or fibrosis, the outflow of bile or pancreatic juice may be compromised[60]. Indeed, studies have shown that separate recording from the pancreatic sphincter in patients with recurrent pancreatitis demonstrates manometric stenosis in the absence of the biliary sphincter[79,80]. There is strong evidence that pancreatic outflow obstruction is the cause of the severe episodic pain in some patients and they benefit from TDS-TAS. In the series of Moody *et al.*[26], 12 of 17 patients with previously unsuccessful but adequate sphincteroplasty obtained pain relief after excision of the septum. The second advantage of surgery over the endoscopic procedure is that a mucosa to mucosa apposition can be obtained. This is important in avoiding further scarring and restenosis of the ampulla[26,81].

It must be emphasized that in many surgical series there is a trend towards a better outcome when a procedure is performed for biliary rather than for pancreatic pathology[60,62,66]. The poorer results in the pancreatic group have been attributed to the presence of underlying parenchymal disease, even when that is not apparent by current imaging techniques[66]. A further distinction in the pancreatic group should be between acute recurrent and chronic pancreatitis, as the former has a significantly better outcome[63]. This is not surprising, in the latter, as the presence of established and radiologically documented parenchymal disease is likely to cause persistent symptoms even after an adequate drainage procedure. According to some authors, patients with chronic pancreatitis are not appropriate candidates for surgery, even when the stenosis is thought to be confined to the transampullary portion of the duct of Wirsung[26,66]. Invariably there are other sites of obstruction of the pancreatic duct proximal to the sphincter which are not appreciated either before or during operation, or there is significant underlying parenchymal disease[66]. In contrast, well selected patients with acute recurrent idiopathic pancreatitis may benefit from sphincteroplasty and septectomy, as has been reported recently by Toouli *et al.*[68]. These authors performed TDS-TAS on 26 patients with idiopathic recurrent pancreatitis strictly selected on the basis of abnormal manometric findings; they reported an excellent result in 15 and mild symptoms in eight patients. The poor results of earlier series are probably due to heterogeneous patient populations, and to inclusion of patients with alcoholic pancreatitis and narcotic dependence[68].

Conclusion

Sphincter of Oddi dysfunction is not a common condition, but it is a challenging one to diagnose and treat. Diagnosis and definition of the disorder often remain elusive or arbitrary. The high failure rate of endoscopic and surgical treatment reflects the difficulties in accurate diagnosis and the lack of specific objective criteria by which to select appropriate therapy. Furthermore, in a subgroup of patients, sphincter dysfunction is simply a part of a generalized gastrointestinal motility disorder; targeting the sphincter does not result in control of the symptoms. All procedures on the sphincter should be undertaken with caution after meticulous investigation, and patient selection should be based on strict objective criteria.

Review

Recent advances in the surgical treatment of faecal incontinence

C. J. VAIZEY, M. A. KAMM and R. J. NICHOLLS

St Mark's Hospital London, Northwick Park, Watford Road, Harrow HA1 3UJ, UK
Correspondence to: Dr M. A. Kamm

Background Improved imaging and refined technology have led to a number of recent advances in the surgical treatment of faecal incontinence.

Methods Original articles, identified using a computer database (Medline), and recently published abstracts of meetings were selected on the basis of greatest clinical relevance; these were reviewed.

Results Ultrasonographic characterization has led to improved therapeutic strategies. Simple structural damage is readily identified and external sphincter repair results in a good outcome for a majority of patients. For more complex structural damage, or for the newly recognized primary internal sphincter degeneration, alternative treatment strategies are emerging. The electrically stimulated gracilis neosphincter and the artificial bowel sphincter offer good results. The latter may be a more simple operation. For structurally intact but weak sphincters, sacral nerve stimulation is a promising therapy. Other therapies, such as antegrade irrigation, may be helpful for patients with neurological disorders.

Conclusion Better imaging, refined classification and new operations are leading to improved surgical techniques for faecal incontinence.

What constitutes optimum surgical treatment of faecal incontinence is rapidly changing. This review examines the most important recent developments, many of which have been aided by improved imaging and refined technology. This is not a systematic review, as only preliminary results are available for many of the procedures cited. However, many of these treatments have demonstrated long-term efficacy in the management of urinary incontinence.

Most patients with faecal incontinence due to simple external anal sphincter structural defects benefit from overlapping sphincter repair[1,2]. The introduction of anal endosonography, with its ability to characterize internal and external sphincter structural damage, has greatly enhanced accurate selection of patients for repair[3]. When failure occurs it can be due to breakdown of the repair[3] or co-existent problems, such as irritable bowel syndrome. In patients with a single defect involving the external sphincter the treatment course is relatively clear. Less clear, however, are the best surgical options for those with weak but intact sphincter muscles, internal anal sphincter defects or complex external sphincter injuries. Some are helped by biofeedback and some by antidiarrhoeal drugs, such as codeine or loperamide, but these are not a satisfactory long-term solution for many.

New treatments are required for patients with intractable faecal incontinence who are not suitable for, or who have failed, simple repair, biofeedback and drug therapy. To avoid a colostomy it is often necessary to perform invasive or major surgery, which may be complex and without the success rates expected from simple repair. At present there is increasing interest in new surgical approaches to faecal incontinence, many of which appear to have encouraging early results. Anorectal physiology studies and endoanal ultrasonography should now be a standard part of preoperative assessment as outcome depends as much on the characterization of the underlying problem and correct choice of operation as it does on surgical technique. In complex cases endoanal magnetic resonance imaging (MRI) may add to information obtained from ultrasonography in defining the external sphincter[4].

Advances in diagnostic imaging of the anal sphincter

The introduction of endoanal ultrasonography in the 1980s radically altered the previously held view that pudendal nerve damage was the underlying cause of faecal incontinence in most patients[5]. Ninety per cent of those presenting with faecal incontinence, in whom the only apparent predisposing factor was childbirth, have detectable structural damage to the external sphincter, internal sphincter, or both[6]. Changes in pudendal nerve function were noted to co-exist with structural damage, the latter accounting for the muscle weakness and incontinence. Ultrasonography has not only defined structural damage to the sphincter complex but has also allowed the recognition of degenerative disorders of the sphincter muscles[7].

MRI using an endoanal coil is not an economically practical substitute for endoanal ultrasonography, but it does provide improved images of the external sphincter and of fistulous tracks. For those who have equivocal findings on ultrasonography or who need further definition of possible sepsis related to faecal incontinence, MRI is a major advance[8,9].

Simple structural defects

The commonest cause of a reparable defect in the anal sphincter muscles is obstetric trauma. Thirty per cent of women after their first vaginal delivery have structural damage to the anal sphincter mechanism which may be seen on endoanal ultrasonography[10] and this increases to 80 per cent following a forceps delivery[11,12]. In primi-

Paper accepted 5 January 1998

parous women studied before and after delivery, both sphincter muscles were structurally affected in 13 per cent of cases, the external sphincter alone in 6 per cent and the internal sphincter alone in 16 per cent[13]. Isolated damage to the internal sphincter is considered to be due to shearing forces as opposed to direct tearing. The perceived high percentage of isolated internal sphincter injuries may change with improving definition of the external sphincter muscle by higher frequency ultrasonography and its excellent definition using endoanal MRI. Where there is a single defined defect involving the external sphincter alone or in combination with the internal sphincter, the operation of choice is overlapping sphincter repair[2,14]; this may be used successfully even in the delayed situation[3] and in the elderly[15]. A non-overlapping repair is employed in the acute situation by many obstetricians and it has been used with some success by surgeons in the non-acute situation[16]. Acute overlapping repair is now preferred by some gynaecologists[17]. In the absence of sepsis, single surgical or traumatic injury to the external or both sphincters can usually be treated in the same manner as obstetric injury, using an overlapping sphincter repair[18].

Weak but intact sphincters

Most patients with faecal incontinence were previously believed to have weak sphincter muscles due to progressive denervation[5,19]. With the advent of endosonography, most of these patients may been shown to have structural damage. In the remainder, primary degeneration and weakness of the internal anal sphincter smooth muscle[7] or weakness of the external striated muscle sphincter are the commonest findings. True isolated neuropathy appears to be rare.

Idiopathic incontinence

Postanal repair. A comparison of treatment modalities for idiopathic faecal incontinence must be preceded by a thorough assessment to exclude sphincter defects or abnormalities, and this must include endoanal ultrasonography[20]. Studies conducted before the availability of this imaging technique[21–23] did not give a totally accurate characterization of the pathology and are probably not as reliable as subsequent studies in which sphincter damage was excluded. As a result of the changed emphasis away from neurogenic injury, the physiological basis for postanal repair is now being questioned. Although short-term benefit occurs in up to 83 per cent of patients, long-term improvement may be present in as few as 28 per cent[24,25] with only 21 per cent fully continent[26]. The addition of internal sphincter plication to a pelvic floor repair confers no benefit and may damage the sphincter muscles, with a fall in mean resting pressure[27]. Total pelvic floor repair or the addition of an anterior levatoplasty and (possibly) external sphincter plication to a postanal repair may improve the results[23,28], but reports contain small patient numbers and short follow-up.

Sacral nerve stimulation. Alternative treatments are needed for patients with weak but intact sphincters. Intermittent direct electrical stimulation of the anal sphincters (via the anal canal) has a limited effect on sphincter function[29,30]. Continuous stimulation of the sacral nerves in the treatment of patients with bladder dysfunction has been used since 1981[31–37]. A recent report[38] describes its use for faecal incontinence in patients with a weak but intact external sphincter. Patients undergo a short trial of stimulation using percutaneous electrodes (usually placed through the S3 foramen) and an external stimulator. If there is symptomatic improvement over several days the patient proceeds to implantation of a permanent electrode and a stimulator, identical to that used for dynamic graciloplasty. The permanent implantation of the electrode is performed through an incision over the sacrum; the leads are tunnelled to the stimulator which is implanted in the anterior abdominal wall. Even after 26 years of experience with this technique in urological practice, the mechanism of action remains unclear, although it appears to alter sacral nerve reflexes rather than to change motor function directly.

In the only published study to date of the application of this technique to the anal sphincter. Matzel *et al.*[38] report a marked improvement in faecal incontinence and external sphincter pressures in three patients who received a permanent implant. Those who might benefit from such treatment, however, remain poorly defined. A detailed study of the short-term effects of sacral nerve stimulation[39] describes a moderate increase in median squeeze pressure with no effect on the resting pressure. Ambulatory studies show decreased rectal contractility and some qualitative changes in resting anal pressure activity. No consistent effect is noted in electrosensitivity or compliance. The increase in squeeze pressure may be secondary to stimulation of α motoneurones and the qualitative changes in ambulatory manometry due to a modulation of sacral nerve reflexes via stimulation of A-δ fibres.

Incontinence associated with specific disorders

Rectal prolapse. Rectal prolapse should be excluded in patients with sphincter weakness without an obvious structural defect. Endoanal ultrasonography can suggest this diagnosis by demonstrating an abnormally thick or thin internal sphincter muscle and subepithelial thickening. Faecal incontinence occurs in 30–80 per cent of patients with full-thickness rectal prolapse[40]. Internal sphincter function recovers after abdominal rectopexy, which may be the only intervention necessary to restore continence[41–44]. Madden *et al.*[42] found that 17 of 23 patients were continent for solid and liquid stool after rectopexy, compared with only eight before surgery. Delemarre *et al.*[44] also found 17 of 23 patients continent for solid and liquid stool after operation, compared with five before surgery. Improvement may be related to removal of the source of persistent rectoanal inhibition[45], or to the prolapse no longer holding the anus open[46,47]. Recovery of continence has also been documented after perineal surgery, such as Delorme's procedure; while the results are probably not as impressive as after rectopexy[48], some reports claim an improvement of up to 83 per cent[49]. Perineal rectosigmoidectomy with levatoplasty results in improvement in continence in 46 per cent[50] to 90 per cent[51] of patients. The technique of laparoscopic rectopexy should have the same effect on continence as its transabdominal predecessor, but no long-term results have yet been published. The management of incontinence persisting after prolapse repair remains difficult. Postanal repair after rectopexy is of limited value; one study describes improvement in seven of nine patients[52] but only two were continent to both solid and liquid stool.

Diabetes mellitus. Incontinent patients with diabetes mellitus have a combination of somatic neurogenic and autonomic dysfunction[53–55] which is not amenable to simple surgical procedures. The long-term benefit of therapies such as biofeedback and sacral nerve stimulation has yet to be determined.

Progressive systemic sclerosis (scleroderma). The most consistent anal lesion encountered in faecal incontinence secondary to systemic sclerosis is marked atrophy of the internal sphincter leading to passive leakage[56]. Constipation resulting from disordered colonic motility may sometimes mask the sphincter weakness. Some patients may also have altered rectal compliance, acquired megacolon or bacterial overgrowth, leading to diarrhoea and greater stress on the sphincter. There is no simple surgical solution for the anal lesion. Those affected also have a higher incidence of rectal prolapse[57].

Spinal injury and other neurological disorders. Faecal incontinence is present in a high proportion of patients with spinal injury[58]. This can be a particular problem after laxative use for constipation, as there is no external sphincter activity to oppose bowel contraction. Faecal incontinence also occurs in about 30 per cent of patients with multiple sclerosis[59]. In both disorders there is often a co-existent problem of constipation, which renders therapy more difficult.

Dynamic graciloplasty is contraindicated in any neurological disease that may involve atrophy of the gracilis muscle. In one report of 12 patients implanted with an artificial bowl sphincter, nine had faecal incontinence secondary to a neurological disorder[60]. These were a prolapsed intervertebral disc (three patients), polyneuropathy (two), benign spinal tumour (one), diabetic neuropathy (one), cerebral trauma (one) and myasthenia gravis (one). The short-term follow-up of these patients showed good results. Direct stimulation of the pudendal nerve is described by Schmidt *et al.*[61] in two incontinent patients with myelomeningocele. It is technically more demanding than sacral nerve stimulation and their long-term results seem disappointing (personal communication, R. A. Schmidt). In patients with intractable bowel problems due to spinal injury, formation of a colostomy can have a dramatic effect on quality of life[62].

Disrupted irreparable sphincters

Disruption of the anal sphincters not amenable to simple repair ranges from a single defect in the internal sphincter to total disruption of the anal sphincter with little or no residual muscle tissue. Internal sphincter defects are often due to common surgical procedures. Endoanal ultrasonography can demonstrate these after operations such as lateral sphincterotomy[63] and anal dilatation[64]. Increasing awareness of the extent and effect of sphincter damage that may be caused by such procedures, together with the availability of sphincter relaxing agents like glyceryl trinitrate ointment[65,66] or injected botulinum toxin[67], may reduce the incidence of this type of incontinence. Less avoidable surgical damage includes injury to the sphincter during the treatment of fistula. Extensive external anal sphincter damage may result from obstetric, surgical or other trauma; it may also follow unsuccessful surgery aimed at sphincter repair. A number of new treatments have been devised for disorders involving extensive or irreparable sphincter damage. Some may also have application in patients with profoundly weak but intact sphincters.

Collagen injection

When the patient has isolated passive leakage, drug therapy in the form of antidiarrhoeal agents is usually the best initial option. Repair of the internal sphincter muscle alone is not successful[68]. There is one report[69] of the use of collagen injection for internal sphincter insufficiency, but long-term results have yet to be established. This and other injectable materials have been used with some success in urinary incontinence[70,71].

Skeletal muscle transposition

When there is severe passive leakage from internal sphincter disruption, severe disruption of both sphincter muscles or failure of a previous repair, a surgical solution may involve replacement of the sphincter muscle with other striated muscle, implantation of an artificial material or the establishment of a colostomy.

The use of skeletal muscle wrapped around the anus to aid continence was first described by Pickrell *et al.*[72] in 1952; these authors used the gracilis muscle. Despite modifications, such as intermittent stimulation, the fast-twitch skeletal muscle could not attain the capacity for prolonged contraction. The procedure was, therefore, reliant to some extent on the muscle being wrapped tightly enough to cause some degree of obstruction. The results were poor[73,74] and the operation fell into disrepute. Other muscles which have also been used to encircle the anus include gluteus maximus[75–78] and obturator internus[79]. Patients may find the gluteus muscles easier to contract than the gracilis as the former are natural synergists of the anal sphincter[80]. However, there may be more of a functional deficit after transposition of the gluteus muscle than after graciloplasty, and the gluteus operation has not achieved better results than unstimulated graciloplasty[81], although the two operations have not been compared directly.

The use of muscle wraps was revived with the discovery that chronic stimulation of a skeletal muscle can convert fast-twitch, fatiguable muscle into slow-twitch, less fatiguable muscle. With chronic stimulation there is an increase in the number of capillaries, an increase in aerobic oxidative capacity and a decrease in muscle fibre diameter. The actual number of muscle fibres remains unchanged[82,83]. The first chronically stimulated graciloplasty was performed in 1986 by Baeten *et al.*[84] in Maastricht. This work, combined with that of Williams and colleagues in London[85], has led to the general acceptance of the 'dynamic graciloplasty' as a treatment option for severe faecal incontinence. Results and complications vary from centre to centre[86,87]. Most surgeons reserve it for patients in whom conventional treatments have been tried or are considered inappropriate. Contraindications to dynamic graciloplasty include perianal sepsis, thereby excluding patients with Crohn's disease. Although no known ill effects have been reported from an active stimulator during pregnancy, it is recommended that the stimulator be turned off. Implanted pacemakers and defibrillators may be subject to interference from the stimulator controlling devices, and so dynamic graciloplasty may not be compatible when these are present. There is, however, one report of a patient who had both a cardiac pacemaker and a magnet-controlled graciloplasty stimulator without problems[88].

Although devascularization of the muscle 4–6 weeks before the gracilis wrap has been recommended[89], this stratagem has been omitted with success[90]. The procedure involves two components which may be performed at one or two operations. The gracilis muscle is traced to its distal attachment to the tibia through a medial incision in the thigh and a separate small incision just below the knee. The tendon is detached at its insertion and the muscle delivered into the thigh wound. Incisions are made laterally on each side of the anus, or anterior and posterior to the anus. A tunnel is created around the anus by finger dissection to accommodate the muscle wrap through 360°. A further track is then created from the perianal tunnel to the top of the thigh incision. The gracilis is then passed to the anal tunnel, wrapped around the anus in a γ, α or ε configuration, and its tendon secured to the contralateral ischial tuberosity.

Implantation of the stimulator and its leads may then be performed at the same or at a later operation. The nerve to the gracilis is located at the top of the thigh using a hand-held nerve stimulator. The electrode may either be in the form of a cuff placed directly around the nerve or a wire placed adjacent to the nerve branches. A pocket is created for the stimulator in the anterior abdominal wall through a transverse incision. The leads are tunnelled from the muscle up to this pocket and attached to the stimulator. The activation of the stimulator is usually delayed 4–6 weeks to allow the muscle to become fixed in its new position and the wounds to heal.

A bilateral gracilis wrap may also be used, but this is usually confined to the creation of a perineal colostomy after abdominoperineal resection for cancer or after extensive perineal trauma. The muscles may be used separately, one to form a neosphincter and the other to form a sling to replace puborectalis[87,91]. Alternatively, they may be used together to encircle the anus, coming from either side, around the back of the perineal colostomy and being joined anteriorly. This latter method of reconstruction has been used with some limited success, even without stimulation[92].

After wound healing an 8-week muscle stimulation programme is commenced on an outpatient basis. The stimulation is gradually increased until continuous stimulation can be applied to the muscle, resulting in sustained contraction. For defaecation the patient must switch off the stimulator to allow the muscle to relax.

Good results are reported in up to 78 per cent of patients who have undergone dynamic graciloplasty with continence for both liquid and solid stool[84,88,92]. The commonest complications are technical problems with the muscle wrap and with muscle stimulation, perianal infection, infection of the stimulator and leads, and anorectal functional imbalance. Such functional imbalance may lead to incontinence or to difficulty with defaecation[93]. Difficulty with defaecation is particularly marked in those with a history of evacuatory problems and in those who have not used the muscles of defaecation over a long period of time. Postoperative re-education about anorectal coordination during defaecation may be helpful.

The technique of graciloplasty continues to evolve. Intramuscular rather than perineural placement of the electrodes can avoid unnecessary exposure of, and therefore damage to, the nerve. A hand-held patient programmer working by telemetry is now replacing the magnets used previously to turn the stimulator on and off. The number of adjustments and hence the number of outpatient visits to convert the muscle to a non-fatiguable state is also being reduced. It may be possible to use another stimulated muscle in the leg if the gracilis is found to be unsuitable, although this is rarely necessary. The neurovascular anatomy of the biceps femoris is compatible with electrical stimulation in 75 per cent of cases[94] but sartorius has an unsuitable neurological supply[95]. The gluteus maximus may be stimulated but it does not function as well as the stimulated gracilis and requires a higher voltage, resulting in a shortening of the lifespan of the stimulator battery.

Artificial bowel sphincter

Experience with the artificial bowel sphincter is in its infancy. The artificial urinary sphincter was introduced in 1972 and is reported to produce total or near-total urinary continence in over 75 per cent of patients and improvement in a further 15 per cent[96]. The urinary sphincter (AMS Sphincter 800; American Medical Systems, Minneapolis, Minnesota, USA) has been used for faecal incontinence, with good result[60,97,98]. In 1996 the artificial bowel sphincter, a version of the artificial urinary sphincter modified to take account of anal anatomy, was introduced. The cuff which surrounds and occludes the anal canal is available in 14 different sizes, including three different widths: a 2-cm (narrow) cuff, a 2·9-cm (standard) cuff and a 3·4-cm (wide) cuff, and cuff lengths ranging from 7 to 12 cm. A pressure-regulating balloon, implanted in the abdominal wall, holds 40 ml of filling fluid and is available in seven different pressure ranges: 51–60 up to 111–120 cmH_2O. The control pump, placed in the labia or scrotum, contains the valves and resistor needed to transfer fluid to and from the cuff. It also has a deactivation button which is used to render the system inactive during the healing phase after operation or when any transanal procedure is to be performed.

The operation is carried out through two incisions, one anterior to the anus and one running transversely in the lower abdomen. A tunnel is created for the cuff in a similar way as for the gracilis muscle wrap. To avoid the possibility of perianal discomfort or cuff erosion, the tunnel should be made high up against the inferior aspect of the levator muscles. A sizer is passed around the anus to allow the correct width and length of cuff to be selected; when the cuff has been placed in position, its tubing is passed up to the lower abdomen and the anal wound is then closed. The balloon and the pump are implanted through the abdominal incision positioned just above the inguinal ligament. The balloon rests immediately behind the rectus muscle and the pump is placed in the labia or scrotum. Aseptic technique and filling the device with the correct volume of fluid without air bubbles are probably the two most vital aspects of this otherwise straightforward operation.

The first results of the European trial of the new AMS artificial bowel sphincter should be available in 1998. There have already been three published studies of anal incontinence treated with the urinary sphincter and modified urinary sphincter, from Christiansen and

Lorentzen[60] (12 patients), Lehur *et al.*[97] (13 patients) and Wong *et al.*[98] (12 patients). The overall success rate was 73 per cent (27 of 37 patients), with 20 patients totally continent of stool at all times and seven with some loss of liquid stool only. The major complications were infection and mechanical failure, both of which occurred in eight of the 37 patients. Only one patient with previous irradiation and scarring had erosion of the device through the perineum. As for graciloplasty, tightening of the anal canal can result in difficulty with defaecation after the procedure.

Colostomy and antegrade irrigation

The option of a colostomy for intractable incontinence should be reserved for those not suitable for conventional surgery and should not be regarded as a treatment failure. For some patients it is the optimal treatment, allowing return to as near normal a lifestyle as possible. Almost a quarter of patients, however, are unable to come to terms with a stoma. Those whose quality of life was poor before operation can often regain a more positive outlook on life[99]. Further improvement of quality of life can often be achieved by stoma irrigation[100]. Irrigation is possible in about 80 per cent of patients receiving a colostomy for cancer and it has been shown to be safe and cost effective[100]. There is no reason why similar figures could not be attained by those whose colostomy is for faecal incontinence.

An alternative strategy for faecal incontinence involves the creation of a proximal colonic stoma through which irrigation is performed to keep the distal bowel empty. The antegrade continence enema has been used in children, especially those with a congenital disorder, via an appendicostomy[101–103]. If the appendix is not available then a tubularized caecal flap can be used[104]. Long-term problems include stenosis at the mucocutaneous junction, reflux of irrigation fluid into the ileum and loss of responsiveness to infused fluid. A valved conduit with skin flaps, using the sigmoid and/or the transverse colon, has also been used; the greatest success has occurred with the transverse colon conduit in adult patients[105,106].

Congenital defects

Faecal incontinence associated with congenital abnormalities is common. It may occur as part of the primary abnormality, or following corrective surgery. Fifty-seven per cent of patients have soiling following a posterior sagittal anorectoplasty for anorectal malformation[107]. Fifty-five per cent of patients with spina bifida soil regularly[108]. Thirty-five per cent of children who have had a Duhamel operation for Hirschsprung's disease are incontinent when assessed at age 4 years or older[109]. Twenty-seven per cent of patients operated on for a benign sacral teratoma in infancy have some faecal soiling[110]. Those with anorectal malformation who have had a pull-through operation should be assessed to determine whether the sphincter muscle surrounds the bowel, using ultrasonography, MRI or electromyographic studies. If the bowel has not been pulled down through the muscle a transposition may be the first choice of procedure before any consideration is given to reconstructive surgery. The hindgut is also commonly abnormal in these patients and requires evaluation.

The 70 per cent success rates reported for dynamic graciloplasty have not been equalled in the group of patients with congenital problems, such as imperforate anus, where this is often an accompanying sensory deficit. In these patients good results can be expected in only about 50 per cent[84]. In the pilot studies of implantation of an artificial bowel sphincter only six of 37 patients had congenital defects and one of the six had cerebral trauma as well[60]. All six appear to have had a good result in the short term.

Conclusion

Successful surgical treatment of faecal incontinence depends on the accurate characterization of the motor, sensory and anatomical integrity of the anal sphincter mechanism. In most cases this can be achieved with a combination of a detailed history, careful examination, anorectal physiological studies and endoanal ultrasonography. In the future, MRI may emerge as a further important means of defining sphincter anatomy. The simplest and most successful surgical procedure is the overlap repair and this should be used as a first option in all patients with a single defect of the external sphincter or of both the external and internal sphincter muscles. More complex procedures have a role in well defined circumstances. Colostomy still has a role when it is desirable to avoid complex surgery.

Simple laparoscopic gastropexy as the initial treatment of paraoesophageal hiatal hernia

A. O. AGWUNOBI, J. BANCEWICZ* and S. E. A. ATTWOOD*

*Departments of Surgery, Royal Albert Edward Infirmary, Wigan and *University of Manchester, Hope Hospital, Salford, UK*
Correspondence to: Mr J. Bancewicz, University of Manchester, Hope Hospital, Stott Lane, Salford M6 8HD, UK

Background Paraoesophageal hiatal hernia is relatively rare compared with sliding hernia but it is associated with serious complications. Its clinical management presents a major challenge since many patients are elderly and unfit for a formal repair. This paper describes a laparoscopic method aimed at reducing the complications of open repair.

Methods Thirteen patients treated for symptomatic paraoesophageal hernia were included in the study. Eleven patients successfully underwent a simple laparoscopic modification of the Boerema anterior gastropexy. Two patients required an open anterior gastropexy through a minilaparotomy because of incomplete reduction of the hernia. A five-puncture technique was used. The stomach and any other contents of the sac were reduced into the abdomen and the stomach was firmly fixed to the fascia of the anterior abdominal wall with GORE-TEX sutures tied extracorporeally.

Results There was one postoperative death due to spontaneous intrathoracic perforation of the posterior aspect of the stomach in an elderly woman with severe cardiac disease. There was no postoperative morbidity. Eight of the ten patients who went home following laparoscopic gastropexy have remained asymptomatic on follow-up. In three patients, two in the laparoscopic group and one in the open group, symptoms recurred.

Conclusion While anterior gastropexy has a significant incidence of recurrent herniation, the clinical results of this simple procedure in a high-risk population support its use as the initial surgical option.

Paraoesophageal hiatal hernia is an uncommon clinical problem accounting for 2–5 per cent of all hernias[1]. Unlike sliding hernia, it is associated with a high incidence of complications and these are often severe and sometimes fatal[2–4]. They include gastric volvulus, obstruction, strangulation with perforation and upper gastrointestinal haemorrhage. For this reason, most authorities agree that the treatment of choice is operative repair. However, the timing of repair and the suitability of the patient for surgery present difficult clinical decisions[3]. In practice, many of those with symptoms are elderly, unfit and a poor risk for formal surgical repair. It is often difficult to judge the relative risks of surgery and of leaving the condition to take its course. These considerations led to the use of a very simple laparoscopic gastropexy in an attempt to improve symptoms and reduce the risk of complications with minimal operative trauma.

Patients and methods

Patients

Thirteen consecutive patients (11 women, two men) presenting with symptomatic paraoesophageal hernia over a 2-year period were studied. Most came from an inner city environment, hence the high prevalence of severe cardiorespiratory disease. The median age was 67 (range 46–87) years. Only two patients were younger than 60 years. Two additional patients presented during this time, but were unsuitable for a laparoscopic operation because of associated intestinal obstruction in one and previous multiple upper abdominal operations in the other. Both underwent conventional open surgical repair.

Eleven patients presented with epigastric and retrosternal pain after meals. Six had dysphagia and only one had heartburn. Gastroscopy was performed in all cases. No patient had oesophagitis. Visualization of the stomach was difficult at endoscopy and the distal stomach could not be seen in six patients because of gastric volvulus. Barium meal examinations were performed in all cases, and demonstrated gastric volvulus in six patients and large paraoesophageal hernias in the remainder. Oesophageal manometry and 24-h oesophageal pH recording were performed in the single patient with heartburn, but no pathological acid reflux was demonstrated.

Surgical technique

General anaesthesia was used throughout. After creating a pneumoperitoneum, a five-puncture approach was used. Cannulas were placed at the umbilicus, the epigastrium, the right upper quadrant, the left upper quadrant and the left flank. In some cases the hernia reduced easily and the port in the left flank was omitted. The hernia was reduced using atraumatic grasping forceps. Two GORE-TEX (W. L. Gore, Woking, UK) sutures were passed through the anterior wall of the stomach and brought out through the port sites in the epigastrium and the left upper quadrant. The sutures were passed through the linea alba or the fascia of the anterior abdominal wall and tied extracorporeally. A small portion of the stomach was herniated into these port sites to ensure firm fixation. This is effectively a modification of the Boerema anterior gastropexy but with suturing of the anterior wall of the fundus rather than the lesser curve of the stomach in the classical Boerema operation. No nasogastric tubes or drains were used.

Presented to the Association of Surgeons of Great Britain and Ireland, Glasgow, UK, May 1996
Paper accepted 14 August 1997

Table 1 Patients and their co-morbidity

Patient no.	Age (years)	Sex	Co-morbidity
1	87	F	Severe angina
2	81	F	CCF
3	75	F	Hypertension
4	74	F	CCF
5	72	F	COAD
6	71	F	COAD
7	67	F	None
8	63	M	COAD
9	62	F	None
10	62	F	None
11	61	F	CCF
12	48	M	Lung cancer
13	46	F	COAD

CCF, congestive cardiac failure; COAD, chronic obstructive airway disease

Results

The status of ten of the 13 patients was American Society of Anesthesiologists grade 3. The associated co-morbidity is listed in *Table 1*.

Eleven patients had a laparoscopic gastropexy completed successfully. Operating time ranged from 25 to 45 min. Two procedures were converted to open minilaparotomy with anterior gastropexy because of incomplete reduction of the hernia. Another patient, who presented as an emergency, had an incomplete reduction, but was deemed unfit for open surgery. Laparoscopic gastropexy of the incompletely reduced stomach was performed, but the patient died 3 days later. Post-mortem examination showed an intrathoracic perforation of the posterior wall of the stomach through an area described by the pathologist as 'gastromalacia'. There were no postoperative complications in the remaining patients.

The most difficult part of the operation was reduction of the hernia. Once reduced it was easy to suture the stomach to the anterior abdominal wall. Oral fluids *ad libitum* were allowed on the first postoperative day and light diet on the second day.

Eight of the 11 patients who had a completely laparoscopic gastropexy have remained asymptomatic on follow-up (median 10 (range 3–24) months). In two patients symptoms have recurred (at 2 and 6 months). Both patients were relatively fit and active compared with the others in the series. One has required formal open repair with good results; the other does not have symptoms severe enough to merit further operation.

Of the two patients who required minilaparotomy, one has had a partial symptomatic recurrence, but is being managed conservatively because of cardiorespiratory insufficiency. The other remains well.

Discussion

The treatment of paraoesophageal hernia in this series presented a significant surgical challenge because of the associated co-morbidity and high operative risk. All of the patients presented with severe symptoms compelling action despite the operative risk. The laparoscopic approach was selected in an attempt to decrease the morbidity associated with upper midline laparotomy. There was only one death in a very unfit elderly patient. It could be argued that in this patient the operation should have been converted to an open procedure, but the patient was considered unlikely to have survived this. Morbidity was otherwise minimal. One patient had incipient respiratory failure and was orthopnoeic. She was miserable with intractable vomiting due to gastric obstruction. Following laparoscopic gastropexy she was completely relieved of the vomiting and returned to community care 5 days later.

Most paraoesophageal hernias are of the mixed type in which the cardia is displaced above the diaphragm. The herniated stomach commonly rotates around its longitudinal axis causing organoaxial volvulus. Less frequently rotation occurs around the transverse axis causing mesentericogastric obstruction which may lead to strangulation, perforation, ulceration and haemorrhage with disastrous consequences. The incidence of these complications has been reported to be as high as 30–45 per cent[2–4] and the mortality rate from emergency operations may be as high as 50 per cent[2].

Prompt repair is therefore desirable in symptomatic patients. In asymptomatic patients, paraoesophageal hernia may be diagnosed incidentally by finding a retrocardiac gas bubble on a chest radiograph. The value of surgery in this group is less clear, but most consider that surgery should be offered to avoid dangerous complications at a later stage.

The present series is similar to others[3] in having a high proportion of elderly patients. The associated co-morbidity led the authors to adopt a minimalist approach to surgery, in the belief that the value of laparoscopic gastropexy is that it is a relatively simple procedure with little or no tissue dissection and little postoperative pain. Provided the hernia contents are completely reduced, it is a safe procedure that is remarkably well tolerated. The recurrences have occurred in the fitter patients in the series and it is tempting to speculate that such a simple gastropexy cannot withstand vigorous activity. Laparoscopic gastropexy is now therefore reserved for those with poor cardiorespiratory status.

The results of simple laparoscopic gastropexy for paraoesophageal hernia in this series compare surprisingly well with those of other methods. There was no associated morbidity in this series compared with a reported morbidity rate of up to 25 per cent[5,6]. Furthermore, eight of 11 patients have complete relief of their obstructive symptoms. However, laparoscopic crural repair is tedious and difficult in patients with these large hernias. For this reason some surgeons have used mesh repair of the hiatus[7], but reservations exist about the use of prosthetic mesh around the oesophagus. Although the crura were not repaired, fixation of the stomach to the anterior abdominal wall effectively seals the hiatus. The presence of gastro-oesophageal reflux is variable in those with paraoesophageal hernia. The symptoms of paraoesophageal hernia in this series were related to obstruction or volvulus rather than reflux, and the primary aim was the correction of obstruction and prevention of further volvulus. This is similar to the experience of Ellis *et al.*[5] and Williamson *et al.*[8]. In patients in whom laparoscopic reduction is not possible, open reduction and gastropexy at minilaparotomy seems a good alternative.

While laparoscopic gastropexy has a significant incidence of recurrent herniation, the clinical results of this very simple procedure in a high-risk population support its use as the initial surgical option in those unfit for major surgery.

Background Pancreatic cancer resection is considered a high-risk procedure in patients aged 70 years or older.

Methods Some 398 patients with pancreatic adenocarcinoma, observed between 1990 and 1995, were reviewed. Operative outcome and survival of 33 patients aged 70 years or more were compared with findings in 85 younger patients who underwent resection.

Results Resectability was not significantly different between the elderly and younger patients; neither were mortality or overall morbidity. However, patients aged 70 years or more had more relaparotomies ($P < 0.01$) and more haemorrhagic complications ($P < 0.001$). Nutritional recovery after resection was satisfying even for elderly patients (body-weight gain and increase in serum albumin concentrations, $P < 0.05$). Univariate analysis showed a moderately poorer survival in the elderly ($P = 0.09$). Multivariate analysis demonstrated that tumour diameter, grading and Union Internacional Contra la Cancrum stage were independent prognostic factors, whereas age was not.

Conclusion Patients aged 70 years or more can benefit from pancreatic cancer resection similarly to younger patients.

Pancreatic cancer has an extremely unfavourable prognosis: it is the fifth commonest cause of cancer death[1] and less than 20 per cent of patients are alive 1 year after diagnosis[2]. Its incidence increases with age[3–7]; in Italy, the cumulative risk for the age group 0–74 years is more than twice that of the group aged 0–64 years, for both men and women[7]. As the size of the elderly population has increased rapidly in recent decades, patients aged more than 70 years with potentially resectable pancreatic cancer will be seen more and more often. The dramatic reduction in the rate of operative complications after major pancreatic surgery that has been reported recently in several selected centres[8–11] is probably driving surgeons to approach pancreatic cancer aggressively in elderly patients as well. However, the cost–efficacy of this treatment, in terms of complications and postoperative survival, has not been discussed extensively.

The aim of this study was to assess how advanced age influences the selection of patients for resection and how it affects the operative and long-term outcome of patients with pancreatic adenocarcinoma.

Patients and methods

Between 1990 and 1995, 398 patients with histologically confirmed pancreatic adenocarcinoma were treated at this hospital; 300 were seen in the Department of Surgery and a further 98 received palliation in non-surgical departments. Demographic, perioperative and pathological data were collected prospectively in the departmental pancreatic surgery database; for patients observed in non-surgical departments, medical charts were reviewed. Some 264 patients were younger than 70 years of age (range 31–69 years) and 134 were 70 years or older (range 70–96 years). In all, 118 patients (29·6 per cent) underwent pancreatic resection: 85 were younger than 70 (mean 57; range 31–69) years and 33 were 70 (mean 74; range 70–83) years or older. The selection of patients for resection was performed by the surgical staff based on the presence of distant metastases, advanced invasion of peripancreatic great vessels or poor general condition.

Pancreaticoduodenectomy was performed in 75 patients aged less than 70 years and in 24 of the older group; total pancreatectomy was performed in one and two patients respectively; the remaining patients underwent distal pancreatectomy.

Operative outcome of patients aged 70 years or more was compared with that of younger patients. Operative mortality was defined as death within 60 days from operation (no operation-related death was observed after this interval).

Postoperative recovery of nutritional parameters was considered as a measure of quality of life: body-weight, expressed as percentage of usual body-weight, and serum albumin concentration were recorded at discharge and 6 months after operation.

Only patients with ductal adenocarcinoma (98 patients) were considered for analysis of postoperative survival, to exclude different histological types that could have a different prognosis. The Union Internacional Contra la Cancrum (UICC) classification[12] was used to define tumour extent; tumour differentiation was determined according to the criteria of Klöppel *et al.*[13]; radicality of the operation was defined according to the UICC-R (residual tumour) classification[14]. Most patients received adjuvant therapy (intraoperative radiotherapy (IORT) as previously described[15], postoperative chemotherapy or radiotherapy); this variable was also considered in the survival analysis.

Statistical analysis was performed with BMDP (Los Angeles, California, USA) statistical software; χ^2, Fisher's exact, Mann–Whitney U and Student's t tests were used as appropriate. Survival curves were calculated according to the Kaplan–Meier method[16]. The log rank test was used to detect differences between curves. A Cox proportional hazards model was used for multivariate analysis of survival[17]. Differences were considered significant when $P < 0.05$. Operative mortality was excluded from the survival analysis.

Results

Resectability

The resectability rate in the group of patients younger than 70 years was 32 per cent, compared with 25 per cent in those aged 70 years or more ($P = 0.3$). Greater selection of patients for resection was observed starting from 80 years of age (resectability rate 11 per cent), whereas those aged 70–79 years had the same rate as younger

Paper accepted 29 September 1997

patients (35 per cent). Poor general condition was the main determinant of the decrease in the resectability rate in patients aged 80 years or more; there was no significant difference in the finding of distant metastases or advanced local infiltration in the different age groups over 60 years (*Table 1*).

Operative results

The operative outcome of patients who underwent resection, for patients of 70 years or more and those less than 70 years, is shown in *Table 2*. Mortality rate and the rate of overall complications were not significantly different between the two groups; however, elderly patients had haemorrhagic complications more frequently than younger ones ($P<0{\cdot}001$) and they had a higher rate of reoperation ($P<0{\cdot}01$). Nevertheless, the postoperative stay and the amount of blood transfused were not significantly different between the two groups. The comparison of possible risk factors (associated disease, Karnofsky status, operative blood loss, operating time) between patients over 70 years with and without complications did not identify any significant predictor of complications.

Table 1 Contraindications for resection in patients with pancreatic adenocarcinoma aged 60 years or more

Nutritional changes

Data were available for 28 patients aged 70 years or more and for 75 aged less than 70 years. A significant increase in body-weight and/or serum albumin concentration was observed in both groups 6 months after discharge. Mean body-weight recovery (percentage of usual body-weight) was 5 per cent for patients aged 70 years or more (87 per cent at discharge *versus* 92 per cent after 6 months, $P<0{\cdot}05$) and 5 per cent for younger patients (88 per cent at discharge *versus* 93 per cent after 6 months, $P<0{\cdot}01$). Mean serum albumin level at discharge was 34 g/l in the older group and 35 g/l in younger patients; after 6 months the values were 38 g/l ($P<0{\cdot}05$) and 39 g/l ($P<0{\cdot}01$) respectively.

Patients with ductal adenocarcinoma

Characteristics of the 98 patients with ductal adenocarcinoma are listed in *Table 3*. With respect to younger patients, those aged 70 years or older had more advanced

Mean (range) tumour diameter (cm)	3·0 (1·4–5·5)	3·8 (1·5–7·0)	< 0·01‡
Mean (range) no. of lymph nodes removed	18 (0–50)	13 (0–35)	0·08‡

Values in parentheses are percentages unless otherwise stated. *Intraoperative radiotherapy (IORT), 15–25 Gy; chemotherapy, two to six courses of 5-fluorouracil 1000 mg per m^2 per day for 5 days plus epirubicin 50 mg/m^2 on day 1; external radiotherapy, 30–45 Gy in 1·8-Gy fractions. †χ^2 test for trend; ‡χ^2 or Student's *t* test as appropriate tumour extent, as shown by tumour diameter ($P < 0\cdot01$) and lymph node involvement ($P = 0\cdot09$), and there was a trend towards poorer tumour differentiation ($P = 0\cdot08$). As regards therapeutic approach, elderly patients had a lower number of lymph nodes removed ($P = 0\cdot08$) and they received adjuvant therapy less frequently than younger patients ($P < 0\cdot05$).

Median survival was 16 (95 per cent confidence interval (c.i.) 14–19) months for patients younger than 70 years and 14 (95 per cent c.i. 8–14) months for older ones ($P = 0\cdot09$). The actuarial survival rate of younger patients at 1, 3 and 5 years was 67, 14 and 9 per cent respectively; for patients aged 70 years or older the survival rate at 1 and 3 years was 53 and 0 per cent.

The following factors were significant predictors of survival by univariate analysis: UICC stage ($P < 0\cdot01$), tumour diameter ($P < 0\cdot01$), histological grading ($P < 0\cdot001$), residual tumour ($P < 0\cdot05$) and the association of IORT with chemotherapy and radiotherapy ($P = 0\cdot05$). Invasion of lymph nodes ($P = 0\cdot14$) and the number of nodes removed ($P = 0\cdot5$) were not significant prognostic indicators. The multivariate analysis of survival, with covariates of age, UICC stage, tumour diameter, grading, residual tumour, lymph node involvement, number of removed nodes and association of IORT with chemotherapy and radiotherapy, indicated that UICC stage (relative risk (RR) 1·59, $P < 0\cdot05$), diameter greater than 3 cm (RR 2·21, $P < 0\cdot01$) and grade (RR 2·65, $P < 0\cdot01$) were independent prognostic factors, whereas the remaining parameters (including age) were not.

Discussion

Life expectancy for the elderly population is getting longer: according to the life tables of the Italian population, the life expectancy of a 70-year-old person is 11·6 years for men and 14·7 years for women; at 80 years the values are 6·4 years for men and 7·9 years for women[18]. Median postoperative survival of patients having a pancreatic cancer resection is 10–18 months[19–22]. It follows that life expectancy could not be a reason for the exclusion of elderly patients with pancreatic cancer from the only chance of cure, which is radical resection.

In the present patients there was no decrease of the resectability rate until the age of 70 years, with a 35 per cent rate of resection in the age group 70–79 years. However, beyond the age of 80 years, the resectability rate dropped to 11 per cent, owing to the poor general condition of these patients. The comparison between patients with and without complications failed to identify clinical factors predicting operative complications.

Until the early 1980s poor results after major pancreatic surgery in the elderly were reported, with mortality rates ranging from 20 to 41 per cent[23–25]. However, improvements in perioperative supportive care, jointly perhaps with a more accurate selection of patients, have overturned these results: operative mortality rates of 10 per cent[26], 9 per cent[27], 6 per cent[28] and even 0 per cent[11,29] have been reported in elderly patients undergoing pancreatic resection.

In the present patients aged 70 years or more the mortality rate was 6 per cent and did not significantly differ from that in younger patients (4 per cent). Also, complications were not significantly more frequent in the older group (39 *versus* 33 per cent). An unexpected finding was the higher rate of haemorrhagic events and reoperation in the elderly patients; however, these complications did not prolong the postoperative stay and the amount of blood transfused was not significantly different between the two groups. A more careful attitude in the elderly may have permitted earlier relaparotomy, with the aim of preventing more severe sequelae.

As well as the complication rate, postoperative quality of life must be considered in the surgical decision regarding pancreatic cancer treatment in the elderly. After operation a significant improvement in nutritional status was observed in both groups, reflecting postoperative well-being in these patients. This suggests that even elderly patients may have improved quality of life after resection of pancreatic cancer.

As expected[19–22], postoperative survival was generally poor in these patients, with a slightly worse survival in patients aged 70 years or more: median survival was 14 months in the elderly and 16 months in younger patients ($P = 0\cdot09$); furthermore, no patient aged over 70 years survived for more than 3 years. However, advanced age did not have an independent negative prognostic role: the survival difference seemed to be determined by a combination of a more aggressive tumour behaviour and a less aggressive therapeutic approach. Patients aged 70 years or older had a greater tumour diameter, a trend towards poorer differentiation and a higher rate of lymph node invasion; these factors are recognized indicators of survival after pancreatic cancer resection[20,21,30–32] and the present experience has confirmed the prognostic role of tumour diameter and grade. A less aggressive therapeutic approach in elderly patients was shown by the smaller number of lymph nodes removed per patient and by the limited number of patients of 70 years or more who received adjuvant therapy. In the authors' experience, the association of IORT with chemotherapy and radiotherapy had a favourable effect on survival. Even though this study was retrospective, and selection of patients for adjuvant therapy cannot be excluded, long-term outcome may have been influenced by a difference in adjunctive treatment between the two groups.

According to this experience, age alone is not a limiting factor for pancreatic cancer resection in patients aged 70 years or more; they can tolerate the operation similarly to younger patients, with a satisfying nutritional recovery and minor changes in postoperative survival.

Background The survival of patients who underwent pancreaticoduodenectomy with or without *en bloc* resection of the superior mesenteric–portal vein (SMPV) confluence for adenocarcinoma of the pancreatic head was compared.

Methods To be considered for surgery, patients were required to fulfil the following computed tomography criteria for resectability: (1) absence of extrapancreatic disease, (2) no evidence of tumour extension to the superior mesenteric artery (SMA) or coeliac axis, and (3) a patent SMPV confluence. Tumour adherence to the superior mesenteric vein (SMV) or SMPV confluence was assessed at operation and *en bloc* venous resection was performed when necessary to achieve complete tumour extirpation.

Results Seventy-five consecutive patients underwent pancreaticoduodenectomy, 44 without venous resection and 31 with *en bloc* resection of the SMPV confluence. There were no perioperative deaths in either group; late (more than 6 months) occlusion of the reconstructed SMPV confluence contributed to the death of two patients. Median survival in the 31 patients who required venous resection at the time of pancreaticoduodenectomy was 22 months, and that for the 44 control patients was 20 months ($P = 0{\cdot}25$).

Conclusion Patients with adenocarcinoma of the pancreatic head who require venous resection during pancreaticoduodenectomy for isolated tumour extension to the SMV or SMPV confluence (in the absence of tumour extension to the SMA or coeliac axis) have a duration of survival no different from that of patients who undergo standard pancreaticoduodenectomy. These data suggest that venous involvement is a function of tumour location rather than an indicator of aggressive tumour biology.

The management of tumour adherence to the lateral wall of the superior mesenteric vein (SMV) or superior mesenteric–portal vein (SMPV) confluence represents the most challenging technical aspect of pancreaticoduodenectomy. This finding, whether unexpected or suggested by preoperative imaging studies, is usually not visible until after pancreatic and gastric transection, a point in the operation at which the surgeon has committed to resection[1]. If tumour is left on the lateral wall of the SMV or SMPV confluence, local recurrence and short survival are to be expected. Recent data have clearly demonstrated that patients who undergo pancreaticoduodenectomy with a positive margin of resection[2–6] have a survival duration similar to that of patients who have locally advanced disease treated nonsurgically with 5-fluorouracil-based chemotherapy and radiation[7]. In contrast, the intraoperative finding of tumour adherence to the SMV or SMPV confluence can be managed by partial or segmental venous resection and reconstruction. However, this allows resection of all gross disease only when tumour adherence is limited to the SMV or SMPV confluence. If tumour extension into the retroperitoneum with encasement of the superior mesenteric artery (SMA) is found, the additional operative time and potential patient morbidity involved in a complicated venous resection and reconstruction are wasted.

Several studies have demonstrated three fundamental principles of vascular resection at the time of pancreaticoduodenectomy. (1) Tumour involvement of the proximal SMA or coeliac axis, in contrast to involvement of the SMPV confluence, usually includes extensive involvement of the mesenteric neural plexus, making it impossible to achieve a negative retroperitoneal margin of excision even with radical resection[8–10]. (2) In contrast to arterial resection, segmental resection of the SMV or SMPV confluence can be performed safely with no increase in perioperative morbidity or mortality rate compared with standard pancreaticoduodenectomy[11,12]. (3) Tumour involvement of the SMPV confluence in the absence of tumour extension to the proximal SMA or coeliac axis is not associated with histopathological variables predictive of a poor prognosis; tumour invasion of the SMV or SMPV confluence appears to be a function of tumour location rather than an indicator of biological aggressiveness[11].

Despite recent reports supporting the safety of venous resection at the time of pancreaticoduodenectomy[12,13], the overall poor prognosis of patients with pancreatic cancer and reports suggesting even shorter survival in patients who undergo venous resection[6,14] have convinced many

---

Paper accepted 18 August 1997

surgeons that isolated involvement of the SMV or SMPV confluence is a contraindication to pancreaticoduodenectomy. In an attempt to prospectively study this controversy, the authors' previous report outlined the anatomical rationale for venous resection and its safety in carefully selected patients[11]. The present study compares the survival of patients who underwent pancreaticoduodenectomy with or without *en bloc* resection of the SMV or SMPV confluence for adenocarcinoma of the pancreatic head. Importantly, all patients underwent standardized preoperative imaging using state-of-the-art contrast-enhanced computed tomography (CT). In contrast to all previously published reports outside of Japan, prospective evaluation of the retroperitoneal margin of excision was performed in all resected specimens.

Patients and methods

Data on all patients who underwent pancreaticoduodenectomy for adenocarcinoma of the pancreatic head or uncinate process from June 1990 to August 1995 were recorded prospectively in the pancreatic tumour database. Standardized preoperative imaging and operative techniques were applied to all patients. Preoperative evaluation included physical examination, chest radiography and contrast-enhanced CT. Angiography and laparoscopy were used selectively. To be considered for operation, all patients were required to fulfil the following CT criteria for resectability[15]: (1) absence of extrapancreatic disease, (2) no evidence of tumour encasement of the SMA or coeliac axis as defined by the presence of a normal fat plane between the tumour and these arterial structures, and (3) a patent SMPV confluence. The study group comprised all patients who required resection (tangential or segmental) of the SMV or SMPV confluence during pancreaticoduodenectomy. The control group comprised all patients who underwent pancreaticoduodenectomy that did not require any type of venous resection or reconstruction. Patients who underwent pancreaticoduodenectomy for diagnoses other than ductal adenocarcinoma were excluded. Also excluded were all patients who underwent operations other than pancreaticoduodenectomy (i.e. total pancreatectomy or distal pancreatectomy).

The majority of patients received adjuvant chemotherapy and radiation therapy (chemoradiation). Radiation therapy was delivered with 18-MeV photons either before operation to a total dose of 50·4 Gy (standard fractionation) or 30·0 Gy (rapid fractionation), or after operation to a total dose of 50·4 Gy. Concurrent with either standard- or rapid-fractionation radiation therapy, 5-fluorouracil was given by continuous infusion at a dose of 300 mg per m^2 per day, 5 days per week, through a central venous catheter[16,17].

All operations were performed using a standardized technique[18]. Tumour adherence to the SMV or SMPV confluence was assessed during surgery, and venous resection was performed if the surgeon was unable to fully mobilize the SMPV confluence from the pancreatic head or uncinate process because of presumed tumour adherence. Reconstruction of the SMPV confluence was performed using one of four techniques. Patients requiring tangential resection of less than one-third of the circumference of the SMPV confluence underwent repair with an autologous saphenous vein patch. Patients requiring segmental resection of the SMV or SMPV confluence had reconstruction with either an autologous internal jugular vein interposition graft, a GORE-TEX interposition graft (W. L. Gore, Flagstaff, Arizona, USA), or with a primary anastomosis without interposition grafting. The majority of patients who underwent primary anastomosis without interposition grafting required splenic vein ligation and division. Inflow occlusion was performed routinely during the period of venous resection and reconstruction; systemic heparinization was used at the discretion of the operating surgeon. Following tumour resection and venous reconstruction, many patients received electron-beam intraoperative radiation therapy; 10 Gy was delivered to the bed of the resected pancreas in a dedicated radiation therapy–surgical suite, obviating patient relocation[19]. All patients who underwent venous resection were begun on aspirin within 24 h of surgery and were requested to take low-dose aspirin 80 mg daily indefinitely. For determining length of hospital stay, the day of surgery was counted as day 1.

For pathological analysis, the operative specimen was oriented and dissected by the surgeon and pathologist in a pathology suite in the operating room complex. The retroperitoneal margin was defined as the soft tissue margin directly adjacent to the proximal 3–4 cm of the SMA. The margin was evaluated by frozen-section microscopic examination of a 2–3-mm full-face (*en face*) section of the margin and interpreted as positive if tumour was seen on this section. Tumour size was calculated following surgical resection by measuring the greatest transverse diameter of the tumour. In patients who had received preoperative chemoradiation this was often difficult, and in some specimens gross tumour could not be demarcated from uninvolved pancreatic parenchyma. Beginning in late 1993, a standardized system for the pathological evaluation of the pancreaticoduodenectomy specimen was performed to include histology of the segment of resected vein to determine the presence or absence of tumour cell infiltration of the vein wall; infiltration was defined as the presence of neoplastic cells within the tunica adventitia and/or tunica media of the vein wall[20]. On completion of pathological analysis, all cases were reviewed by a single histopathologist (K.R.C.).

Following the completion of all treatment, patients were evaluated by physical examination, chest radiography and thin-section, contrast-enhanced CT every 3–4 months. The venous phase of the most recently obtained CT scan was used to assess SMPV patency in patients who underwent venous resection. The reconstructed SMPV confluence was judged to be patent if the shape, contour and enhancement of the vessel were uniform from the level of the hepatic hilum to the level of the tributaries of the SMV. The SMPV confluence was judged to be patent but stenotic if the vessel contour was irregular and enhancement visible, but not uniform, throughout the region of venous reconstruction. The SMPV confluence was considered occluded if the vein could not be visualized or thrombus could be identified in the region of venous reconstruction. When the SMV or SMPV confluence was occluded, enlarged venous tributaries were often present in the small bowel mesentery and the mesocolon. All scans were interpreted by a single diagnostic radiologist (C.C.).

Statistical comparisons between groups were by χ^2 analysis of two-way frequencies and Student's two-tailed t test of differences between means. Overall survival analysis was by Kaplan–Meier product-limit estimation, and comparison of overall survival rates between groups was performed using log rank analysis. $P < 0·05$ was considered statistically significant.

Results

Seventy-five consecutive patients with adenocarcinoma of pancreatic head origin underwent either pancreaticoduodenectomy (44) or pancreaticoduodenectomy with *en bloc* resection of the SMV or SMPV confluence (31). There were 42 men and 33 women with a median age of 65 (range 42–81) years. The two treatment groups were similar with respect to sex, age, number of patients who underwent reoperative pancreaticoduodenectomy following a non-therapeutic laparotomy before referral to this institution, and the number of patients who received chemoradiation either before or after pancreaticoduodenectomy (*Table 1*). A significantly larger proportion of patients in the control group (36 of 44) than in the venous resection group (14 of 31) received intraoperative radiation ($P < 0·01$), possibly because of an initial reluctance to utilize intraoperative radiation following reconstruction of the SMV or SMPV confluence.

Operative and pathological characteristics are listed in *Table 2*. There were no perioperative treatment-related deaths, and all patients were successfully discharged from the hospital after a median hospital stay of 16 days for those who underwent venous resection and 15 days for those in the control group. The need for venous resection was associated with a significant increase in operative blood loss ($P < 0·001$). Median tumour size was significantly larger in patients who underwent venous resection ($P = 0·02$). No patient was found to have a grossly positive retroperitoneal margin of excision, and there was no difference in the frequency of microscopically positive retroperitoneal margins between treatment groups. Following the adoption of a standardized pathological examination, the most recent 18 operative specimens from patients who required segmental venous resection were evaluated pathologically for histological evidence of tumour invasion of the wall of the SMV or SMPV[20]. Adenocarcinoma was found to invade the vein wall in 13 of 18 specimens. Neoplastic cells penetrated into or through the tunica media in 12 of 13 specimens and were confined to the tunica adventitia in only one specimen.

Median hospital stay (days)	16	15	0·93

Values in parentheses are percentages. *In-hospital or within 30 days of surgery

In patients who underwent venous resection, left internal jugular vein interposition grafting was the preferred method of reconstruction (*Table 3*). The infrequent use of tangential excision with saphenous vein (patch) repair suggests that most patients had apparent tumour involvement of greater than one-third of the circumference of the vein wall. As demonstrated in *Table 3*, patency rates were quite high when autologous tissue was used for reconstruction. Of the 11 patients who underwent internal jugular vein interposition grafting, nine were evaluable for graft patency. Three of the nine patients are dead from disease (at 13, 13 and 24 months from diagnosis), and six are alive with follow-up ranging from 12 to 37 months; all grafts were patent on the most recent contrast-enhanced CT scans.

A total of seven patients were documented to have occlusion of the reconstructed SMV or SMPV confluence (*Table 3*). Local tumour recurrence as a cause of venous occlusion could not be documented by CT or autopsy in any of these patients. Occlusion of the SMV or SMPV confluence was asymptomatic in five patients but directly related to the cause of death in two patients (8 and 16 months following pancreaticoduodenectomy). Both of these patients developed intractable ascites (cytology negative) and nutritional depletion, and one required emergency splenectomy for upper gastrointestinal haemorrhage secondary to sinistral portal hypertension.

Table 3 Method of venous reconstruction and patency at last follow-up

		Status of SMPV confluence		
Method of reconstruction	Total no. of patients	Patent	Patent with probable stenosis	Occluded
Saphenous vein patch	4 (13)*	2	0	1
Primary end-to-end anastomosis with ligation and division of the splenic vein	8 (26)	3	2	3

GORE-TEX interposition graft	1 (3)	0	0	1
Total	31	16 (57)	5 (18)	7 (25)

Values in parentheses are percentages. *Includes one patient who could not be evaluated because follow-up radiographic images (performed elsewhere) were inadequate for assessment of graft patency. †Includes one patient who could not be evaluated who died from gastrointestinal haemorrhage secondary to a presumed marginal ulcer before undergoing adequate follow-up radiographic imaging. SMPV, superior mesenteric–portal vein

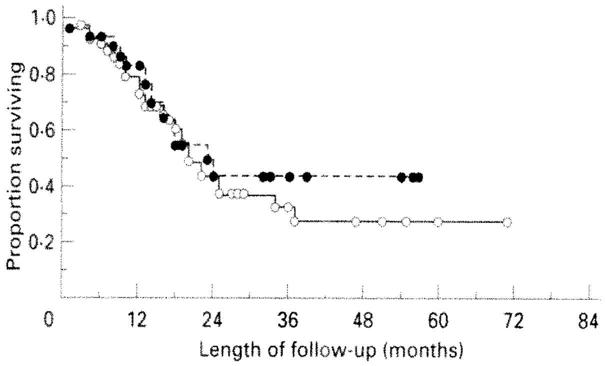

Fig. 1 Actuarial survival for 31 patients who underwent pancreaticoduodenectomy with venous resection (●) and 44 control patients who underwent standard pancreaticoduodenectomy (○). $P = 0{\cdot}25$ (log rank test)

Median follow-up was 17 months; minimum follow-up for all patients was 12 months. Overall median survival for the 75 patients was 21 months. Median survival in the 31 patients who required venous resection at the time of pancreaticoduodenectomy was 22 months and that for the 44 control patients was 20 months ($P = 0{\cdot}25$) (*Fig. 1*).

Discussion

The survival time of patients with adenocarcinoma of the pancreatic head who required *en bloc* resection of the SMV or SMPV confluence at the time of pancreaticoduodenectomy was no different from that of patients who underwent standard pancreaticoduodenectomy. This is consistent with the hypothesis that tumour adherence to or invasion of the SMPV confluence is a function of tumour location and possibly tumour size but not a prognostic factor associated with early tumour recurrence and short patient survival[11]. However, in contrast to previous reports on venous resection during pancreaticoduodenectomy, all patients in the present study underwent high-quality contrast-enhanced CT before tumour resection to ensure the presence of a normal fat plane between the tumour and the proximal SMA and coeliac axis origin. This vital tumour–vessel relationship must be assessed before operation. When assessed at the time of surgery, the relationship of the tumour to the proximal SMA can be examined directly only during the final step in tumour resection, following gastric and pancreatic transection. Furthermore, if the SMV or SMPV confluence is inseparable from the tumour, the proximal SMA cannot be accessed in the absence of interposition grafting (and medial retraction of the grafted SMPV confluence), or division of the splenic vein and lateral retraction of the specimen and attached SMPV confluence[1,21]. In either case, the surgeon has committed to venous resection and completion of pancreaticoduodenectomy even if tumour encasement of the SMA is found, in which case gross tumour will be left behind along the proximal SMA. A fundamental principle of venous resection at the time of pancreaticoduodenectomy is to operate only on patients who have no evidence of arterial involvement (*Fig. 2*). The Japanese experience with regional pancreatectomy clearly demonstrates that patients who have positive resection margins following even extended resection experience early tumour recurrence and short survival[22,23]. American and European data[2–6] also support a short survival time if tumour remains in the retroperitoneum along the proximal SMA following pancreaticoduodenectomy, regardless of whether a segment of SMV or portal vein was removed.

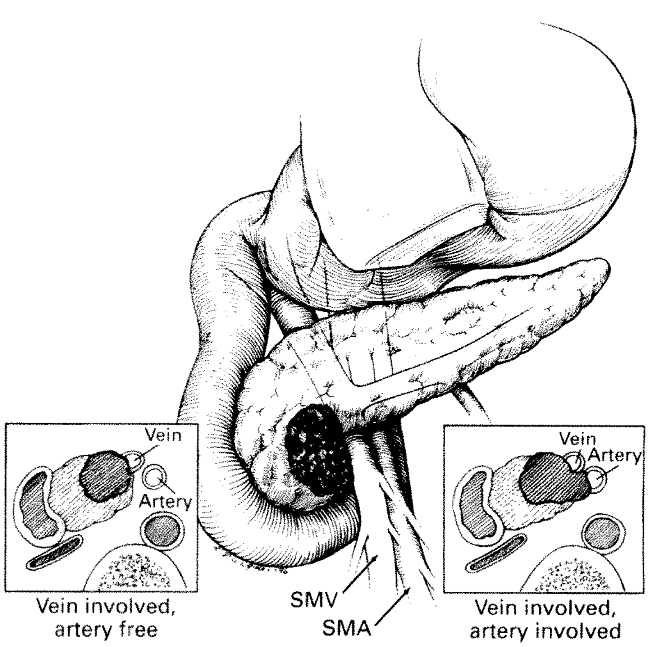

Fig. 2 Illustration of tumours in the pancreatic head involving the superior mesenteric vein (SMV) with and without invasion of the superior mesenteric artery (SMA). Attempted pancreaticoduodenectomy with resection of the SMV in the presence of tumour extension to the SMA will result in short patient survival; this is related to the surgeon's inability to achieve a negative retroperitoneal margin of resection and probably unrelated to whether or not a segment of SMV is removed

In the absence of information about prospective evaluation of the retroperitoneal margin (along the proximal SMA), reports of venous resection during pancreaticoduodenectomy are impossible to interpret. The lack of accurate evaluation of the retroperitoneal margin of resection and the high frequency of positive margins in patients who underwent venous resection (*Table 4*)[4,6,12–14,24–26] suggest that the majority of these patients had locally advanced tumours with arterial encasement and were poor candidates for pancreaticoduodenectomy. For example, Roder and colleagues[14] concluded that resection of the SMV or portal vein in patients with pancreatic adenocarcinoma was associated with a poor prognosis as demonstrated by a median survival of only 8 months. They concluded appropriately that their short patient survival was due to an incomplete resection (positive margin) in 15 of 22 patients. However, they provided no data to support the implication that the need for venous resection predicts margin positivity; that would be true only for patients with tumour extension to the proximal SMA, a finding that can be accurately assessed before operation with contrast-enhanced helical CT. Such patients should not undergo attempted pancreaticoduodenectomy; their locally advanced disease is currently best treated by chemoradiation, systemic gemcitabine or phase II investigational agents.

In this study, objective radiographic (CT) criteria were used for operation based on the belief that there is a fundamental difference between tumour involvement of

the SMPV confluence and tumour involvement of the SMA[11]. The SMV is typically in direct contact with the pancreatic head and uncinate process and lacks an investing sheath of perivascular neural tissues. This allows direct extension to and invasion of the SMV or SMPV confluence by strategically located tumours even in the absence of tumour extension to the SMA. In contrast, the SMA lies posterior and medial to the SMV and is surrounded by the mesenteric neural plexus, a 2–4-mm investing sheath that extends laterally to the posterior aspect of the pancreatic head and uncinate process, and superiorly to the right and left coeliac ganglia[27]. Involvement of the SMA by a tumour in the pancreatic head or uncinate process defines locally advanced disease; the propensity for pancreatic adenocarcinoma to spread along perineural planes makes negative-margin resection unlikely in such cases even with arterial resection. Resection of the SMPV confluence should, therefore, be undertaken only in highly selected patients predicted to have venous but not arterial involvement based on preoperative contrast-enhanced CT. A high rate of negative-margin resections and the possibility of long-term survival may be anticipated only in this group.

Ishikawa and colleagues[28] recently published a system for angiographic typing of the degree of SMPV invasion by adenocarcinoma of the pancreas. They classified the contour of the SMPV confluence on the venous phase of the SMA angiogram based on the extent of presumed tumour invasion: type I, no invasion (normal venous phase); types II and III, abnormalities suggesting tumour invasion limited to the right lateral wall of the SMV or SMPV confluence; and types IV and V, bilateral invasion of the SMV or SMPV confluence. Patients with unilateral (semicircular) venous invasion (types I, II and III) had a 3-year survival rate of 59 per cent, whereas patients with bilateral venous invasion (types IV and V) all died within 18 months of pancreatectomy and had a median survival similar to that of patients who did not undergo pancreatic resection. Similar results were subsequently reported by Nakao and colleagues[29]. While these authors did not examine the retroperitoneal margin of resection as defined in this report, their results were exactly as one would predict based on the assumption that patients with angiograms demonstrating type IV or V disease probably had tumour extension to the SMA and probably underwent incomplete resections. A working knowledge of the three-dimensional anatomy of the SMA and SMV is critical for the pancreatic surgeon; tumours that extend to the left (medial) of the SMV on the venous phase of the SMA angiogram will virtually always involve the SMA. The proximity of the SMA to the posterior–medial aspect of the SMV is a constant anatomical finding easily seen on high-quality CT (*Fig. 3*).

In the present report, histological evidence of tumour invasion into the resected vein was seen in 13 of 18 specimens examined. This is in agreement with the findings of previous authors[23,30] and suggests that the surgeon's intraoperative assessment that venous resection is necessary to achieve complete tumour extirpation is correct in the majority of cases. Importantly, a previous report demonstrated that in 83 per cent of patients, contrast-enhanced CT correctly predicted the need for venous resection, as indicated by the presence of direct adherence of the low-density tumour to the lateral wall of the SMV or SMPV confluence[11].

The technical details of segmental resection of the SMPV confluence have been reviewed previously[18,21]. When tumour invasion of the SMPV confluence prevents mobilization and medial retraction of the SMPV confluence from the pancreatic head and uncinate process, access to the SMA origin and completion of the retroperitoneal dissection can be achieved in one of two ways: ligation and division of the splenic vein or venous resection and reconstruction. Division of the splenic vein at its junction with the SMPV confluence allows access to the origin of the SMA medial to the SMV and provides increased mobility of the portal vein, enabling a primary venous anastomosis to be constructed without tension[31]. However, splenic vein ligation occasionally results in gastrointestinal haemorrhage due to sinistral portal hypertension; one such case occurred in this study. Maintaining an intact splenic vein–portal vein junction has two important consequences in terms of surgical strategy. First, the intact splenic vein–portal vein junction significantly limits the mobilization of the portal vein and prevents primary anastomosis between the SMV and portal vein unless excision of the SMV is limited to less than 2 cm. Second, maintenance of an intact splenic vein prevents direct access to the proximal SMA, making completion of the retroperitoneal dissection impossible in most patients. This difficulty is circumvented by performing venous resection and reconstruction with autologous internal jugular vein before completion of the retroperitoneal dissection and removal of the specimen (*Fig. 4*). Placement of the interposition graft effectively restores a mobile length of SMV, which can then be retracted medially (to the patient's left), allowing retroperitoneal dissection along the origin of the SMA to be completed in the usual manner. Inflow occlusion during the time of venous resection and reconstruction is critical to prevent small bowel oedema.

In summary, these data suggest that venous resection during pancreaticoduodenectomy for adenocarcinoma of the pancreatic head is associated with a survival duration no different from that of patients who undergo standard pancreaticoduodenectomy. However, this conclusion is based on a programme of standardized preoperative imaging (staging) and operative technique. Future studies

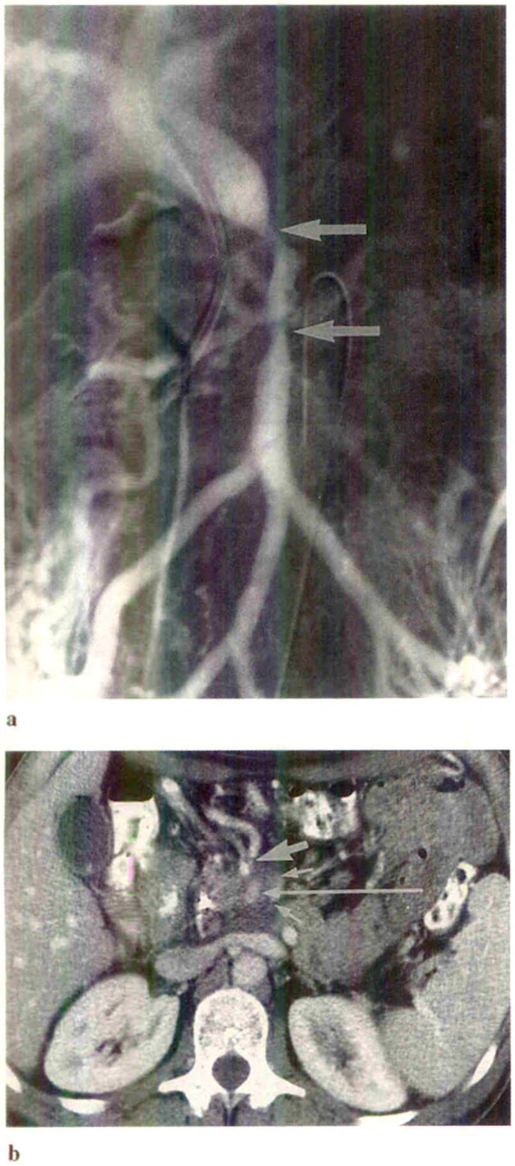

Fig. 3 **a** Venous phase of the superior mesenteric artery angiogram demonstrating bilateral narrowing of the superior mesenteric vein (SMV) (arrows). **b** Contrast-enhanced helical computed tomography in the same patient demonstrating tumour encasement (small arrows) of both the SMV (large arrow) and the superior mesenteric artery (long arrow). Bilateral narrowing of the SMV or superior mesenteric–portal vein confluence on angiography should always raise the possibility of tumour extension to the proximal superior mesenteric artery or coeliac axis. Note the dilatation of the middle colic vein due to significant narrowing of the SMV

examining this question must include similar objective criteria for operation combined with a standardized approach to pathological evaluation of the resected specimen.

Background In acute pancreatitis, two different types of secretory phospholipase A_2 (PLA_2) have been found: pancreatic type I PLA_2 and non-pancreatic type II PLA_2. In this study a potent new PLA_2 inhibitor effective against type II PLA_2 was used in an experimental model of acute pancreatitis.

Methods In 70 rats the efficacy of the compound was analysed in two experimental models of acute pancreatitis: cerulein- and taurocholate-induced acute pancreatitis, imitating mild and severe disease respectively. Serum rat type I PLA_2 protein concentration and type I and type II PLA_2 catalytic activities were measured while giving the inhibitor therapeutically. In a prophylactic protocol the effect on histology was analysed.

Results In the taurocholate model, type II PLA_2 activity was found to be nine-fold higher than in the cerulein model ($P < 0{\cdot}002$), whereas the activity of type I PLA_2 was not increased. The inhibitor significantly decreased serum type II PLA_2 activity in the taurocholate model of acute pancreatitis ($P < 0{\cdot}05$) but type I PLA_2 protein concentration and type I PLA_2 activity were not affected. The inhibitor also reduced histological tissue damage, with significant differences at 3 and 12 h ($P < 0{\cdot}01$).

Conclusion The PLA_2 inhibitor significantly reduced type II PLA_2 activity and was able to protect the pancreas against tissue damage. PLA_2 inhibition offers the possibility of a treatment for acute pancreatitis.

There is evidence that phospholipase A_2 (PLA_2) plays an important pathophysiological role in various inflammatory diseases, such as septic shock[1], adult respiratory distress syndrome[2], multiple injuries[3], diffuse peritonitis[4,5], and acute pancreatitis[6–8]. In human acute pancreatitis, highly significant increases in serum catalytic PLA_2 activity have been found which correlate well with the severity of the disease. However, measurement of pancreatic PLA_2 protein concentration has no prognostic value in acute pancreatitis, suggesting that there are two different types of PLA_2[6,8].

Meanwhile, two types of secretory PLA_2 have been identified: (1) the pancreatic type I PLA_2, with a disulphide bridge between cysteine at position 11 and cysteine at position 77, secreted by acinar cells; and (2) the non-pancreatic type II PLA_2, which lacks these cysteines and the corresponding disulphide bridge[9,10]. From human and experimental data it seems likely that type II PLA_2 plays the major pathophysiological role in acute pancreatitis[8,11].

With regard to a specific medical treatment for acute pancreatitis, various therapeutic approaches and innovative new agents have thus far proven ineffective[12,13]. The objective of this study was to examine the efficacy of a new low molecular weight PLA_2 inhibitor in two different experimental models of acute pancreatitis, simulating mild (oedema) and severe (necrosis) courses of the disease. Two questions were raised: first, whether effective inhibition of serum type II PLA_2 activity *in vivo* can be achieved and second, whether the inhibitor affects tissue damage in the pancreas.

Materials and methods

Seventy female Wistar rats, weighing 260–320 g, were used for the study. Approval for the experiments was obtained from the Animal Ethics Committee of the University of Bern.

Serum and tissue enzymes in cerulein-induced acute pancreatitis

The model of supramaximal stimulation of exocrine pancreatic secretion by the secretagogue cerulein (Takus; Farmitalia Carlo Erba, Bremen, Germany) in a dose of 5 μg per kg body-weight per h with a rate of 0·6 ml/h for 2 h was used to induce mild acute pancreatitis[14]. Immediately before cerulein administration, and at 3, 6 and 12 h after beginning of infusion, blood was taken via an implanted central venous catheter. The PLA_2 inhibitor was given intravenously 10 min (16 mg per kg body-weight) and 4 h (8 mg per kg body-weight) after the end of cerulein infusion. Twenty animals were used in this experiment: ten were untreated and ten were treated with the inhibitor. Rats without the inhibitor received an equal amount of 0·9 per cent sodium chloride solution.

After 12 h the whole pancreas was removed and immediately frozen in liquid nitrogen. After homogenization, lyophilization, dilution and centrifugation at 22 000 r.p.m. for 1 h at 4°C, PLA_2 enzyme concentration and activities were determined in the supernatants.

Serum and tissue enzymes in sodium taurocholate-induced acute pancreatitis

This experimental group also consisted of 20 animals: ten with the PLA_2 inhibitor and ten without. In these rats, acinar cell

damage of necrotizing acute pancreatitis was induced by pressure-controlled (30 cmH$_2$O) intraductal injection of 3 per cent sodium taurocholate solution (Sigma, St Louis, Missouri, USA) in a dose of 0·1 ml per 100 g body-weight. Details have been given elsewhere[11,15]. The inhibitor was given intravenously 10 min (16 mg per body-weight) and 6 and 12 h (9 mg per kg body-weight) after the induction of acute pancreatitis. Blood samples were taken before the induction of acute pancreatitis and at 3, 6, 12, 18 and 24 h afterwards via an implanted central venous line. Animals not receiving the inhibitor were given an equal amount of 0·9 per cent sodium chloride solution. After 24 h the whole pancreas was removed and treated as in cerulein-induced acute pancreatitis.

Biochemical analysis of serum and pancreatic tissue

Rat pancreatic or type I PLA$_2$ protein concentration in its active or inactive form was measured with a time-resolved fluoroimmunoassay. The assay has been described in detail elsewhere[16]. The lowest type I PLA$_2$ protein concentration measurable with the assay is 0·25 ng/ml.

Measurement of lipase activity was performed with a commercially available enzymatic test kit (Monotest 10 Lipase, Boehringer Mannheim, Germany) adapted to the Hitachi 717 (Beckmann, München, Germany). The principle of the method has been given in detail elsewhere[17].

The total catalytic PLA$_2$ activity and type I and type II PLA$_2$ activities were measured with an *Escherichia coli* assay, based on the hydrolysis of phospholipids from [1-^{14}C]oleic acid-labelled *E. coli* membranes in the sn-2 position. Details of this bioassay are given elsewhere[18]. Differentiation into type I PLA$_2$ and type II PLA$_2$ activity was done using the different physiological properties of these enzymes. In contrast to type II PLA$_2$, type I PLA$_2$ is heat-stable at 60°C for 1 h[18,19]. Therefore, the heat-stable type I PLA$_2$ activity was measured in samples after heat treatment by the *E. coli* method, and type II PLA$_2$ activity was calculated by subtraction of type I PLA$_2$ from total PLA$_2$ activity (type II PLA$_2$ = total PLA$_2$ − type I PLA$_2$)[11,20].

Histomorphology in sodium taurocholate-induced acute pancreatitis

Thirty animals were used for histological assessment of the pancreas: 15 untreated and 15 treated with the inhibitor. Each of these groups was divided into three subgroups of five animals each. The inhibitor was given intravenously 10 min (32 mg per kg body-weight) before the induction of taurocholate acute pancreatitis and afterwards at 1·5 h (8 mg per kg body-weight) and 6 h (16 mg per kg body-weight). After either 15 min, 3 h or 12 h, the whole pancreas was removed, fixed in formalin and subdivided into four pancreatic segments (duodenal, biliary, gastric and lienal). The formalin-fixed tissue was embedded in paraffin, cut into 5-mm thick sections, and stained with haematoxylin and eosin. Histological findings were analysed using the method developed by Spormann *et al.*[21].

Characteristics of the phospholipase A$_2$ inhibitor

In vitro experiments with the new low molecular weight PLA$_2$ inhibitor (341·83 Da; BM 16.2056; Boehringer Mannheim) showed inhibitory capacities of 86 per cent against type I PLA$_2$ and of 100 per cent against type II PLA$_2$. The carrageenin–oedema model in the rat revealed marked anti-inflammatory effects at doses of 10–40 mg per kg body-weight per day[22,23]. Therefore, the above-mentioned dosages were used and repeated based on the fact that the PLA$_2$ inhibitor has been found to have a short serum half-life of approximately 10 min.

Statistical analysis

As the data were not distributed normally, all results are given as medians with lower and upper quartiles. Statistical differences between the groups were tested with the Wilcoxon test for paired and unpaired samples. $P < 0·05$ was considered statistically significant.

Results

Serum type I phospholipase A$_2$ protein concentration and lipase activity

In cerulein-induced acute pancreatitis the median peaks of type I PLA$_2$ protein concentration and lipase activity in untreated animals at 3 h were higher than in taurocholate-induced acute pancreatitis (type I PLA$_2$: cerulein 3355 ng/ml *versus* taurocholate 666 ng/ml, $P < 0·002$; lipase activity: cerulein 4540 units/l *versus* taurocholate 3020 units/l, P not significant) (*Table 1*). In both models no differences in the median levels of type I PLA$_2$ protein concentration and lipase activity were found for animals whether or not they were treated with the PLA$_2$ inhibitor, indicating that this compound did not interfere with the systemic uptake and/or synthesis of these enzymes.

Serum total phospholipase A$_2$ activity, type I and type II phospholipase A$_2$ activity

In untreated rats, median total PLA$_2$ activity at 3 h was significantly raised in taurocholate-induced acute pancreatitis (total PLA$_2$ activity: cerulein 7·2 units/l *versus* taurocholate 32·4 units/l, $P < 0·002$) (*Figs 1* and *2*). In cerulein-induced acute pancreatitis the increase in total PLA$_2$ activity was due to the increase in type I PLA$_2$ activity, whereas type II PLA$_2$ activity was found to be

Values are median with lower and upper quartiles. PLA$_2$, phospholipase A$_2$

unchanged (*Table 2*). In contrast to the cerulein model, median type I PLA_2 activity after 3 h was only slightly increased in taurocholate-induced acute pancreatitis, whereas type II PLA_2 activity was found to be increased nine-fold (type I PLA_2 activity: cerulein 4·5 units/l *versus* taurocholate 0·9 units/l, $P<0·002$; type II PLA_2 activity: 3·5 *versus* 31·1 units/l respectively, $P<0·002$).

Some 3 h after application of the PLA_2 inhibitor, a significant inhibition of total PLA_2 activity was found in cerulein-induced acute pancreatitis ($P<0·05$) (*Fig. 1*). Differential analysis of the two types of PLA_2 activity in cerulein-induced acute pancreatitis showed that the significant difference between the groups receiving and not receiving the inhibitor was caused by inhibition of type II PLA_2. In this mild model of acute pancreatitis, no inhibition of type I PLA_2 activity was demonstrated. In taurocholate-induced acute pancreatitis, total and type II PLA_2 activity were significantly inhibited through the application of the PLA_2 inhibitor at 3 h ($P<0·002$), 6 h ($P<0·002$), 12 h ($P<0·05$) and 18 h ($P<0·01$) (*Fig. 2*). As in cerulein-induced acute pancreatitis, type I PLA_2 activity was not inhibited in this severe model of acute pancreatitis.

Tissue enzyme analysis

In the removed rat pancreas with cerulein-induced acute pancreatitis, there were significant increases in type I PLA_2 protein concentrations and type I PLA_2 activity after 12 h in comparison with normal pancreatic tissue, whereas type II PLA_2 activity remained unchanged (type I PLA_2 protein concentration: normal pancreas 500 ng/mg *versus* cerulein 1120 ng/mg, $P<0·05$; type I PLA_2 activity: normal pancreas 0·8 units/g *versus* cerulein 23 units/g, $P<0·002$; type II PLA_2: normal pancreas 36 units/g *versus* cerulein 40 units/g, P not significant). In this mild model of acute pancreatitis no differences were found between animals with or without the PLA_2 inhibitor (*Fig. 3a*).

In the pancreas of rats with taurocholate-induced acute pancreatitis, however, differences were seen between animals with and without the inhibitor. Without the inhibitor, type I PLA_2 protein concentration and type I and type II PLA_2 activity were significantly reduced in comparison with the normal pancreas after the 24-h observation period (type I PLA_2 protein concentration: normal pancreas 500 ng/mg *versus* taurocholate 308 ng/mg, $P<0·002$; type I PLA_2 activity: normal pancreas 0·8 units/g *versus* taurocholate 0·1 units/g, $P<0·002$; type II PLA_2 activity: normal 36 units/g *versus* taurocholate 15 units/g,

$P<0\cdot002$). In taurocholate-induced acute pancreatitis, type I PLA$_2$ protein concentration and type I PLA$_2$ activity in the pancreas of the animals treated with the PLA$_2$ inhibitor were significantly raised ($P<0\cdot01$) compared with values in untreated animals, and values were similar to those seen in the normal pancreas (*Fig. 3b*).

Histomorphology

Over time, there was increased tissue destruction and inflammation in untreated animals with taurocholate-induced acute pancreatitis, whereas changes were moderate in rats treated with the PLA$_2$ inhibitor, especially in the peripheral segments III and IV. In segments I and II, the sites of disease induction, animals in the treated and untreated groups showed similar histological changes during the observation period, as expected (upper range in *Fig. 4*). In segment IV, tissue destruction was reduced by the inhibitor (lower range in *Fig. 4*). Significant differences between the two groups were found ($P<0\cdot01$) for the median sum in the Spormann histological scores (including oedema, pancreatic parenchymal necrosis, fat necrosis, inflammation and haemorrhage) in segment III at 3 and 12 h.

Discussion

Acute pancreatitis is classified clinically into mild and severe forms[24]. The majority of patients suffer from mild acute pancreatitis, a self-limiting disease which responds well to conservative treatment. Up to 20 per cent of patients with acute pancreatitis, however, proceed to a clinically severe form involving both pancreatic and extrapancreatic necrosis, with systemic inflammatory response syndrome and organ complications. Although the initial steps in the pathogenesis of acute pancreatitis are not fully understood, the term 'autodigestion', introduced by Chiari in 1896, summarizes the prevailing concept that the acute inflammation is triggered by the activation of digestive enzymes[25,26]. Protease inhibitors (such as aprotinin and gabexate mesilate), hormones (such as calcitonin, glucagon and somatostatin) and atropine have been studied clinically as possible specific treatments for acute pancreatitis, without success[12,13,27].

PLA$_2$ is the key enzyme in arachidonic acid metabolism, and causes the release of eicosanoids[28]. The enzyme is believed to play an important part in acute inflammatory diseases[1–8]. In acute pancreatitis, increased serum PLA$_2$ activity has been found to correlate with the severity of the disease and the pulmonary impairment[6–8]. On the other hand, measures of pancreatic PLA$_2$ protein concentration have shown no relationship, making it probable that there are two different PLA$_2$ isoenzymes. Indeed, two different types of secretory PLA$_2$ are currently recognized: type I PLA$_2$, which is pancreatic in origin, and type II PLA$_2$, stemming from a non-pancreatic source[9].

Type I PLA$_2$ has been reported to have little activity in hydrolysing cell membranes and in inducing severe inflammatory reactions[29–31], and recent published investigations indicate that the non-pancreatic type II PLA$_2$ plays the central role in the development of local and systemic complications in human acute pancreatitis[4,6–8,32]. The present findings showed marked changes in type II PLA$_2$ activity 3 h after administration of 3 per cent sodium taurocholate stimulating severe acute pancreatitis, whereas type I PLA$_2$ activity did not change significantly.

Kawai *et al.*[33] reported similar findings for a 5 per cent solution of sodium taurocholate with a similar method for the measurement of PLA_2 activity[33]. These findings and the present results indicate that the increase in total PLA_2 activity is caused by the increase in type II PLA_2 activity in the severe model of acute pancreatitis.

In the cerulein model, type II PLA_2 activity showed no change either during cerulein infusion or within the first 12 h. In contrast, in this model the type I PLA_2 protein concentration and type I PLA_2 activity in serum and pancreatic tissue increased rapidly after the induction of acute pancreatitis, with peak values after 3 h. However, these increases in type I PLA_2 had no influence on clinical course or histomorphological findings, which further supports the theory that circulatory as well as local pancreatic PLA_2 is harmless in humans and animals[29–31].

In taurocholate-induced acute pancreatitis, the new low molecular weight PLA_2 inhibitor caused a significant decrease in total PLA_2 activity, mainly by decreasing type II PLA_2 activity. In untreated rats in the cerulein model of acute pancreatitis, where only type I PLA_2 activity increased while type II PLA_2 activity remained constant, there was a decrease in total PLA_2 activity owing to the inhibition of type II PLA_2 activity. Therefore, the PLA_2 inhibitor seems to act mainly on the type II PLA_2 isoform, although *in vitro* studies have shown an additional inhibitory capacity against pancreatic PLA_2 activity.

The decreased levels of type I PLA_2 protein concentration in the tissues and the activities of type I and type II PLA_2 24 h after the induction of acute pancreatitis with sodium taurocholate are explainable by denaturation and inactivation of the enzyme proteins in the necrotic and acid milieu. Support for this theory comes from studies of the enzymes in pancreatic necrosis in human acute pancreatitis. The lowest PLA_2 activity was found in specimens with total pancreatic necrosis[34]. In contrast, tissue type I PLA_2 protein concentration and type I PLA_2 activity in this severe model of acute pancreatitis were unchanged in animals treated with the PLA_2 inhibitor, and were comparable to those found in normal pancreas. This points to the fact that the inhibitor, as a result of its inhibition of type II PLA_2 activity, has the potential for protecting acinar cells from destruction, which may explain the unchanged type I PLA_2 protein concentration and type I PLA_2 activity. This theory is also supported by histomorphological analysis, in which tissue damage and inflammatory reactions remained significant under the influence of the PLA_2 inhibitor.

Findings in the present study lead to the following conclusions. Non-pancreatic type II PLA_2 in both human and experimental severe acute pancreatitis plays an important pathophysiological role. The new low molecular weight PLA_2 inhibitor decreases total catalytic PLA_2 activity. This decrease is caused by the inhibition of non-pancreatic type II PLA_2 activity. The PLA_2 inhibitor reduces tissue destruction and protects pancreatic acinar cells. These findings are important because there is currently no specific treatment available for acute pancreatitis in humans[12,13,27]. This PLA_2 inhibitor holds promise as a treatment for acute pancreatitis and warrants further investigation.

Acknowledgements

The authors are most grateful to U. Tibes, W. Scheuer and W.-G. Friebe from the Department of Preclinical, Biochemical and Chemical Research, Boehringer Mannheim, Mannheim, Germany, for their support with the low molecular weight PLA_2 inhibitor (BM 16.2056) and to Jeannie Wurz for excellent editorial assistance.

Laparoscopic cholangiography: a prospective study

A. J. SABHARWAL, E. J. MINFORD, L. P. MARSON, I. M. MUIR, D. HILL and C. D. AULD

Department of Surgery, Dumfries and Galloway Royal Infirmary, Dumfries DG1 4AP, UK

Background The place of cholangiography has been controversial in the conventional and now in the laparoscopic setting. The aim of this study was to evaluate laparoscopic cholangiography and compare use of a portable C-arm image intensifier with conventional radiography.

Methods One hundred and ninety-seven consecutive patients undergoing laparoscopic cholecystectomy were randomized before operation to cholangiography by either C-arm image intensifier or conventional radiography. Data were collected on a pro forma completed immediately after the operation.

Results Cholangiography was successful in 93·0 per cent of patients. Cholangiography with an image intensifier was significantly faster. In 19 patients the ductal system was obscured by a cannula; in 17 of these cases a metal cannula was used. In 31·6 per cent of patients the clip on the cystic duct was within 1 cm or less of the common bile duct (CBD).

Conclusion Laparoscopic cholangiography is a safe procedure. Use of an image intensifier should be the preferred method of obtaining images. Metal cannulas are more likely to obscure the ductal system. The proximity of the clip on the cystic duct to the CBD highlights the potential for injury caused by electrocautery or erroneous clip application.

Ever since Mirizzi described the first operative cholangiogram in 1937[1] the subject has evoked considerable interest. In recent years the debate has centred around whether laparoscopic cholangiography should be performed selectively or routinely. Grace *et al.*[2] felt that peroperative cholangiography may be indicated in selected patients at risk of common bile duct (CBD) stones or in those in whom the biliary anatomy is unclear. Others, however, subscribe to the view that it sets operative priorities and improves surgical skill and technique[3].

In a recent survey of surgeons carrying out laparoscopic cholecystectomy, however, only 15 per cent undertook routine cholangiography, 33 per cent performed cholangiography selectively and 52 per cent never performed the procedure[4].

As well as the detection of unsuspected ductal stones[5], proponents of laparoscopic cholangiography also cite identification of variations in biliary anatomy[6,7], the reduction in risk of CBD injury[8] as well as the detection of unsuspected operative damage at an early stage in support of laparoscopic cholangiography. A recent study by Kullman *et al.*[9] suggested that early detection of injury led to prompt repair and thereby a reduction in the morbidity associated with a delayed diagnosis.

The aim of this study was to evaluate laparoscopic cholangiography by comparing use of a portable C-arm image intensifier with conventional radiography.

Patients and methods

Some 197 consecutive patients undergoing laparoscopic cholecystectomy by two surgeons (C.D.A., I.M.M.) between September 1992 and January 1995 were included in the study. There were 38 men (mean age 59 (range 24–80) years) and 159 women (mean age 52 (range 17–83) years).

A selective policy of endoscopic retrograde cholangiopancreatography (ERCP) was practised in patients with the standard risk factors for CBD stones[10]. The patients were randomized before operation by opening envelopes to determine the method of cholangiography. Cholangiography was performed, either with a C-arm image intensifier (Stenoscop 9000, IGE Medical Systems, Loncin, Belgium) or by conventional radiography.

Following insertion of a 14-Fr Quickcath (Baxters, Norfolk, UK) percutaneously, a standardized technique of cholangiography was used for all patients[11]. A 4-Fr umbilical catheter (Portex, Hythe, UK) was manipulated into the cystic duct and held in place by a loosely applied ligaclip. Contrast medium (Sodium diatrizoate; Schering, Berlin, Germany) was injected and two films taken as routine for either mode of cholangiography. Traction on the gallbladder was not applied at the time of cholangiography.

Image magnification was minimized by using the maximum focus–film distance and the minimum subject–film distance, and by obtaining all image intensifier hard copies on the largest available field size. The hard copy films were subsequently reviewed independently by a radiologist (D.H.).

Data were collected on a pro forma which was completed by the surgeon immediately after each operation. The mode of cholangiography, the success of the procedure and reasons for failure were noted. The time required for the procedure (insertion of Quickcath to visualization of the biliary system), as well as the completeness of cholangiogram (visualization of intrahepatic/extrahepatic ducts and duodenum), were recorded. The distance between the cystic duct clip and CBD was documented, as were the detection of CBD stones and anatomical anomalies.

Results

In 11 of the 197 patients, cholangiography was not attempted but in eight of these patients conversion took place before Calot's triangle was exposed. In a further 13 patients, cholangiography was attempted but unsuccessful for reasons outlined in *Table 1*, resulting in a success rate of 93·0 per cent. Of the 173 patients for whom successful cholangiograms were obtained, 83 had been randomized

Total	13

Table 2 Duration of laparoscopic cholangiography and operation using either image intensifier or standard radiography

	Image intensifier	Standard radiography
Cholangiography (min)	15 (7–30)	23 (10–50)*
Operation (min)	71 (29–140)	80 (35–140)

Values are mean (range). $^*P<0.0001$ *versus* image intensifier (unpaired t test)

previously to image intensifier and 90 to conventional radiography.

The mean times required for cholangiography and the duration of the operation are shown in *Table 2*. The difference in times for cholangiography were statistically significant ($P<0.0001$, unpaired t test).

The surgeon assessed the images to be complete in 90 per cent of cases in which the image intensifier was used and 86 per cent with conventional radiography, whereas the radiologist's assessment was 81 and 82 per cent respectively. The radiologist, however, did not have the benefit of real-time imaging in assessing the images obtained with the intensifier.

The cannula obscured part of the duct system in 19 patients, but in only two of these was a disposable cannula used. (The type of cannula used was determined by the routine practice of the two surgeons.) In 14 patients (15·6 per cent) more than the standard two images were required and in the majority of cases this was because of incorrect positioning of the patient or resiting of the cannula in the conventional radiography group.

The distance between the ligaclip on the cystic duct to the CBD was measured from the radiographic films of both groups. The 'critical length' was recorded in 165 cases, in eight of the 173 successful laparoscopic cholangiographies the operator omitted to record the distance. In almost one-third of cases (31·6 per cent) the 'critical length' was 1 cm or less. There was no correlation between 'critical length' and conversion rate (*Fig. 1*).

Fourteen patients were found to have CBD calculi at the time of operation. Three of these had had a mildly raised alkaline phosphatase level at the time of initial presentation but the level had returned to normal before operation. One patient had had jaundice before admission and had undergone ERCP and sphincterotomy. The remaining ten had no clinical or biochemical features to suggest CBD stones. Of the 14 cases, five were converted to an open procedure after calculi were revealed and six were successfully dealt with by postoperative ERCP. In three of the patients the operation had already been converted to an open procedure for other reasons when calculi were discovered. The overall conversion rate was 10·2 per cent (*Table 3*). There were no negative bile duct explorations in the study and none of the patients have returned with calculi during follow-up.

Table 3 Reasons for conversion from laparoscopic to open cholecystectomy

	No. of operations
Unclear anatomy	7
CBD stones	5
Bleeding	3
Adhesions	2
Cystic duct transected	2
CBD injury	1
Total	20 (10·2)

Values in parentheses are percentages. CBD, common bile duct

Although subjective, in terms of technical difficulty, the laparoscopic cholangiography procedure was considered 'easy' in 59 per cent of cases by the operator, 'moderately difficult' in 29 per cent and 'difficult' in 12 per cent.

Discussion

The success rate for cholangiography of 93·0 per cent is in keeping with other studies[6,12,13], although it has been postulated that success rates will increase with greater experience in the procedure[10]. It is acknowledged that variations in technique exist[14] although it has not been determined as yet which one should be adopted universally.

Laparoscopic cholangiography may have a place in the detection of unsuspected CBD stones. Despite a selective ERCP policy the present incidence of CBD calculi at operation was 7 per cent but this is in agreement with other series[15,16]. The relevance of discovering clinically unsuspected stones during routine laparoscopic cholangiography has been questioned in the presence of an effective ERCP service[17], but the optimum management of these stones will no doubt continue to evolve for the foreseeable future with the refinement and likely establishment of laparoscopic exploration of the CBD.

It has been suggested that fluoroscopy should reduce the time required for cholangiography compared with standard radiography[17] and this has been substantiated in the present study. Although there does not seem to be a difference in the completeness of cholangiogram obtained by either method, fluoroscopy offered more versatility by real-time imaging. For example, the table can be tilted and drugs such as glucagon or morphine administered to improve filling and drainage of the complete biliary tree.

Misinterpretation of a cholangiogram may occur when an incomplete examination of the entire biliary tree has been accepted[18]. Over 80 per cent of these cholangiograms were considered complete. A scoring system[19] to assess quality of cholangiogram was not employed in this study, but both surgeon and radiologist used the same criteria to determine completeness and there were no significant differences in their findings. However, metal cannulas were far more likely to obscure the image than disposable cannulas, especially in conventional radiographic imaging.

The major concern during laparoscopic cholecystectomy is iatrogenic bile duct injury, and careful dissection and clear visualization of the anatomy are of paramount importance; despite this the actual junction of the cystic duct and CBD may not be seen easily. A problem in this critical area has been alluded to[13] where a short cystic duct and subsequent superolateral retraction of the gallbladder causes 'tenting' of the CBD, which can be mistaken for the cystic duct and clipped. The present study draws attention to the distance between the clip on the cystic duct and the CBD as this may be important in laparoscopic dissection. The use of electrocautery, for example, before clip application highlights the importance of being confident in the local anatomy if thermal injury to the CBD is to be avoided, bearing in mind that injury can be caused either directly during dissection (immediate perforation) or by secondary extension of thermal damage (delayed perforation)[20]. Open cholecystectomy series report an injury rate to the CBD of 0·2 per cent, whereas the best figures for laparoscopic work remain above 0·3 per cent[21]. While some claim that cholangiography will reduce the rate of CBD injury[22] others suggest that it is more likely to lead to early detection of such injury[23], and there are those who feel that routine use of cholangiography does not prevent it[2]. One CBD injury occurred in this study and cholangiography led to immediate recognition of the injury.

The conversion rate of 10·2 per cent was perhaps a little higher than reported previously[24,25], but there does seem to have been a reduction as the study progressed. Mitchell *et al.*[26] stated that cholangiography is more difficult in the laparoscopic setting, but the present study suggests that the laparoscopic surgeon can carry out this procedure without too much difficulty.

Laparoscopic cholangiography is a safe procedure and, even if not used routinely, every surgeon practising laparoscopic cholecystectomy should have the ability to perform the technique. This study shows that cholangiography with an image intensifier is preferable to standard radiography and metal cannulas should be avoided.

Background Bile leaks and bile duct strictures are major complications of cholecystectomy which increased in incidence after the introduction of laparoscopic surgery. The management and outcome of these complications following the introduction of laparoscopic cholecystectomy was reviewed.

Methods Eighteen patients of median age 45 (range 22–70) years were treated between January 1992 and December 1995. Six patients had a common hepatic duct (CHD) stricture, four following a failed previous repair. Nine patients had bile leaks from bile duct transection (four), cystic stump (four) or segment V duct (one). Two patients had partial bile duct damage with primary sutured repair at time of cholecystectomy. One patient had recurrent haemobilia from a hepatic artery pseudoaneurysm.

Results Cystic stump or segment V leaks were treated successfully by endoscopic stenting (median follow-up 42 months). Roux loop biliary reconstruction was carried out in nine patients: two CHD strictures, three of the four failed primary CHD repairs and four bile duct transections. All had normal liver function test results at median follow-up of 30 months. The two patients with partial duct injuries repaired at initial surgery required no further intervention. The right hepatic artery aneurysm was successfully embolized. There have been no deaths or major complications of endoscopic, radiological or surgical intervention.

Conclusion Endoscopic stenting successfully treats cystic stump and segment V duct leaks. Duct strictures, including failed initial repairs and transections, have a good outcome with Roux-en-Y loop reconstruction.

Laparoscopic cholecystectomy has become the preferred treatment of symptomatic gallstones since its introduction in the UK in 1990. However, prospective audits reported a fourfold to eightfold increase in biliary complications compared with those seen in the 'open' era[1,2]. Whether this is related to the technique *per se* or is merely associated with a surgical 'learning curve' has not been established. The mechanism and nature of biliary complications following laparoscopic surgery are different from those at open surgery[3]. Their management and outcome therefore require the same critical evaluation as the introduction of the procedure itself[1,2]. An analysis was made of the management and outcome of patients with biliary complications over a 4-year period following the widespread introduction of laparoscopic cholecystectomy.

Patients and methods

Data were reviewed on all patients with a biliary complication of laparoscopic cholecystectomy treated in this institution between January 1992 and December 1995. Complete data capture was ensured by referring to the computer database for endoscopic retrograde cholangiopancreatography (ERCP) and to the radiology database for percutaneous transhepatic cholangiography (PTC).

Eighteen patients were treated over this 4-year period. Patient characteristics, cholecystectomy details, nature of the biliary complication and previous biliary surgery are shown in *Table 1*. Eight laparoscopic cholecystectomies had been performed by consultants and ten by higher surgical trainees. All were done electively but three had evidence of acute cholecystitis at operation, confirmed by subsequent histological examination. Intraoperative cholangiography (IOC) had been performed in four patients. Of these, two developed a cystic duct stump leak (patients 3 and 4), one had a partial transection of the common hepatic duct (CHD) which was noted on IOC and repaired by primary suture (patient 14), and the fourth patient had normal IOC findings but subsequent complete transection of the CHD (patient 10). One patient had undergone preoperative ERCP and stone removal.

In six patients the biliary complication was noted at laparoscopic cholecystectomy (patients 13–18). These patients had conversion to an open operation and primary repair was performed (*Table 1*). In-patient stay in this group ranged from 7 days to 2 months (median 2 weeks). Four of these patients required further management following a failed primary repair with onset of jaundice or cholangitis due to anastomotic stricturing.

In 12 patients laparoscopic cholecystectomy had been completed. In three patients some difficulty had been encountered as a result of adhesions (one) or bleeding (two). Nine of the 12 patients in this group had been discharged from hospital (on postoperative days 2–12) and three were transferred directly for further management. Five of the 12 patients had undergone exploratory laparotomy for a suspected bile leak before referral (patients 2, 4, 6, 11 and 12). None had undergone full cholangiography before laparotomy. A bile leak was

18	Cholangitis	Stricture of initial repair	Percutaneous balloon dilatation at 17 and 58 months	60

*Three-monthly symptom review and liver function tests. RUQ, right upper quadrant; CHD, common hepatic duct; RHD, right hepatic duct; RHA, right hepatic artery confirmed in four of the five patients, but in only one was the site of leak identified and secured. Patients in this group were referred between 3 days and 11 months after laparoscopic cholecystectomy and 1–21 (median 3) days after a biliary complication was suspected. Laparotomy findings are also shown in *Table 1*.

Results

The indication for referral, clinical and radiological findings, treatment and outcome of the patient group are given in *Table 2*.

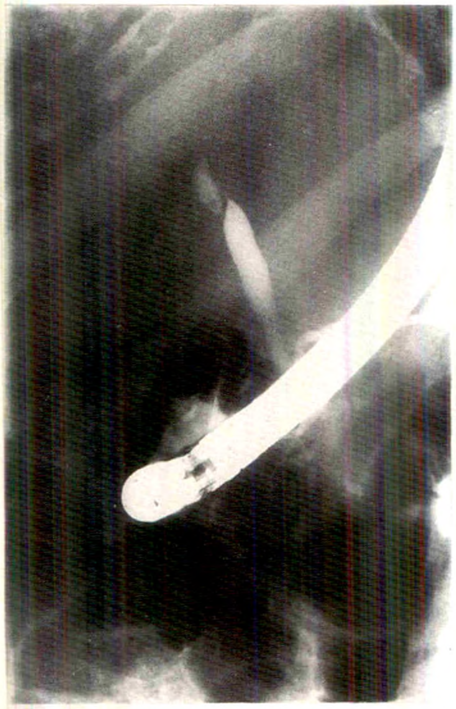

Fig. 1 Endoscopic retrograde cholangiopancreatography demonstrating complete occlusion of the common hepatic duct. There is no visualization of the intrahepatic bile ducts and therefore percutaneous cholangiography is essential to establish the extent of biliary injury

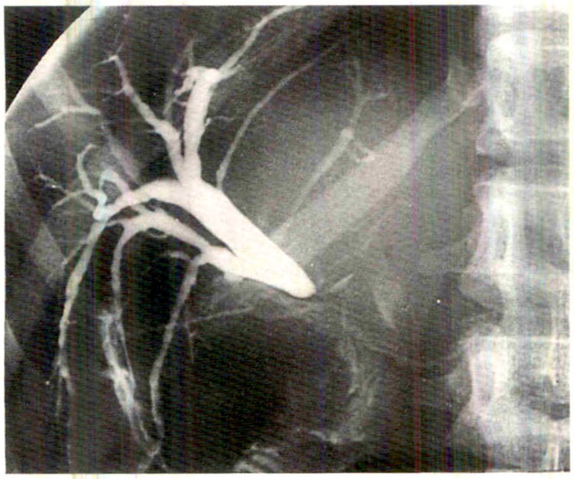

Fig. 2 Percutaneous transhepatic cholangiography demonstrating a stricture at the site of a biliary–enteric anastomosis. The stricture developed following a bile leak at the initial anastomosis

Abdominal ultrasonography was performed following admission in 15 patients. Of the nine patients with bile leaks (patients 1–5 and 9–12), subhepatic collections were found in four (drained percutaneously) and generalized free fluid in three. Dilated intrahepatic ducts were found in all six patients with bile duct strictures (patients 7, 8 and 15–18).

ERCP was performed in 13 patients and established the nature of the biliary complication in six. Patients in whom ERCP showed complete biliary obstruction (*Fig. 1*) proceeded to PTC to demonstrate the intrahepatic bile ducts (*Fig. 2*). PTC successfully demonstrated the entire intrahepatic biliary tree in eight patients with no associated complications. Selective angiography was performed in eight patients and showed right hepatic artery pseudoaneurysm in one (patient 6) and occlusion in three (*Fig. 3*).

Of the five patients with cystic stump or segment V bile leaks, one was successfully identified and secured at laparotomy before referral. The other four underwent percutaneous drainage of collections along with

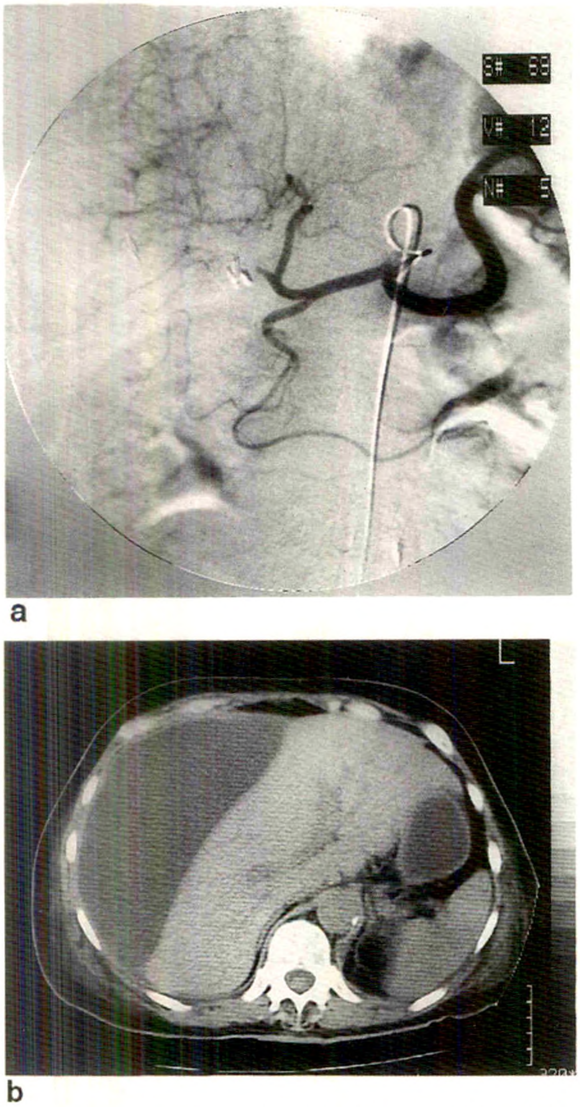

Fig. 3 **a** Selective hepatic angiography demonstrating a right hepatic artery occlusion from a clip. **b** The associated computed tomogram demonstrating right lobe atrophy and a subphrenic bile collection

endoscopic insertion of a nasobiliary drain (three patients), followed by stenting (four) for a period of 6–8 weeks. There were no immediate or subsequent treatment-related complications (median follow-up 42 (range 18–48) months).

Biliary reconstruction was performed in nine patients. Two had bile duct strictures (patients 7 and 8), four had complete bile duct transection (patients 9–12) and three had a failed previous biliary reconstruction and anastomotic stricturing (patients 15–17). Reconstruction was by Roux-en-Y hepaticojejunostomy in all cases with formation of a percutaneous access loop in patients with Bismuth type IV[4] injuries (five patients). Eight of the nine patients are asymptomatic and have had no further biliary complications (median follow-up 30 (range 16–60) months). All have normal liver function. One patient (no. 17), who was referred following failed initial Roux loop repair, has had persistent pain which improved following percutaneous balloon dilatation of a radiological stricture at the right hepaticojejunal anastomosis.

Biliary balloon dilatation was used in three patients with strictures. One failed after 2 months (patient 8) with subsequent Roux loop reconstruction. Two were successful (patients 17 and 18) with a follow-up of 12 and 58 months.

In the patient with recurrent haemobilia (patient 6), selective angiography revealed a right hepatic artery pseudoaneurysm which was successfuly treated by transarterial coil embolization (follow-up 18 months). Two patients (nos 13 and 14) referred for evaluation following an operative partial injury to the bile duct required no further treatment.

Discussion

Prospective audits in England and Wales[2], the west of Scotland[1,5] and the Netherlands[6] have reported biliary injury rates following laparoscopic cholecystectomy of 0·3–0·8 per cent, similar to those found in large series from Europe (0·33 per cent)[7] and the USA (0·25 per cent[8] and 0·5 per cent[9]) but higher than the one in 1000 bile duct injury rate reported by selected centres with open cholecystectomy[10–13]. Referral centres have also reported an increase in bile duct injuries following the introduction of laparoscopic cholecystectomy[6,14,15]. However, some single-centre comparisons have shown no increase in complications and reduced morbidity and mortality rates associated with the laparoscopic procedure[16,17], and more recent regional cholecystectomy audits have shown an incidence of bile duct injuries similar to that of open surgery[5,18]. The present study provides no insight into the true incidence of bile duct injuries in the UK, as most patients were referred only after a failed initial attempt at bile duct repair or failure to control a bile leak.

The immediate management of patients found to have a bile duct injury at the time of laparoscopic cholecystectomy is controversial. Primary suture for a localized injury to the bile duct was satisfactory in this and other studies[18,19], although the late development of strictures is well recognized[20]. With complete duct transections, primary duct to duct repair is associated with a high failure rate, as seen in two patients in the present series and in 13 in the series of Stewart and Way[19,21,22]. A primary Roux-en-Y repair has been reported as satisfactory from the audit by Russell and colleagues[18]. However, a failed Roux loop repair leading to a bile leak and subsequent stricture, as found in one of the present patients, considerably increases the difficulty of obtaining a satisfactory outcome from revisional biliary surgery[19]. If expertise in forming a Roux-en-Y loop to a non-dilated bile duct is not available, biliary drainage and transfer to a hepatobiliary centre may be advisable.

There has been much debate on the value of IOC. Supporters stress that surgically relevant biliary tract anomalies are common[23]. Only one patient in the present series had a major biliary tract anomaly and the injury was unrelated to this[24]. In one patient IOC demonstrated a bile duct injury allowing primary duct repair over a T tube. Routine IOC increases the time required for cholecystectomy and is associated with a small risk of biliary complications[25]. However, it would ensure the earlier detection of some bile duct injuries and hence improve the overall results of surgical treatment[23]. The technique used for laparoscopic cholecystectomy may be a more important factor in the prevention of bile duct injuries[26].

In this study the majority of biliary complications were detected in the early postoperative period, although in three-quarters this was after discharge from hospital. An occult presentation can occur even with major bile duct injuries[24,27] and a delay in diagnosis and satisfactory treatment is a considerable disadvantage to the long-term outcome of bile duct injuries[4,28]. In this series, referral occurred promptly at a median of 3 days (range from 1 day to 3 weeks) after a biliary tract complication was suspected.

The importance of cholangiographic assessment before surgery for a biliary tract complication has been emphasized previously by Stewart and Way, duct repair failing if no or incomplete cholangiography was obtained before operation[19]. Of the four patients in this series who underwent further surgery for bile leakage before referral, this was successful in one; the other patients achieved only drainage of bile collections. None had undergone cholangiography.

The authors have found oral and intravenous contrast-enhanced computed tomography to be useful in detecting previously undrained collections and lobar liver atrophy associated with vascular occlusion[29]. Selective hepatic angiography was performed in eight patients, of whom four had significant findings including a right hepatic artery occlusion in three and an aneurysym of the right hepatic artery in one. Vascular occlusion was associated with more severe injuries to the biliary tract, three of the four patients having Bismuth type IV duct damage[30], for which reconstruction is reported to be less successful[19,31]. Experience of this problem in liver transplantation may be an advantage in the management of these bile duct injuries[32–36]. Haemobilia is an unusual complication of laparoscopic cholecystectomy[37], although pseudoaneurysm of the right hepatic artery has been reported[38–43] and most have been treated successfully by embolization.

The definitive treatment of bile duct injuries remains controversial. In this and previous studies bile leak from the cystic duct stump has been managed successfully by endoscopic stenting, endoscopic sphincterotomy alone being unsatisfactory[31]. With common bile duct injuries some groups support the use of endoscopic biliary stents[31], others suggesting that this merely delays satisfactory surgical treatment[19]. In the present series a Roux-en-Y jejunal loop without stenting was used for strictures or transection of the bile duct[19,22,44,45]. Although long-term follow-up data are required, excellent initial results have been obtained with surgical reconstruction for major bile duct injuries (median follow-up 30 months) and endoscopic stenting for cystic stump or segment V duct leaks (median follow-up 42 months). There have been no deaths or major complications.

Mortality following elective infrarenal aortic reconstruction: a Joint Vascular Research Group study

R. B. GALLAND

Department of Surgery, Royal Berkshire Hospital, London Road, Reading RG1 5AN, UK
Correspondence to: Mr R. B. Galland

Background This study aimed to define the cause of death in patients undergoing elective infrarenal aortic reconstruction.

Methods Members of the Joint Vascular Research Group who had collected details prospectively of patients undergoing elective aortic reconstruction provided information on those who died.

Results Details of 3786 patients were obtained. Some 171 patients died (133 following abdominal aortic aneurysm (AAA) and 38 after aortofemoral bifurcation graft (AFBG) for occlusive disease). The mortality rate following AAA repair was 4·8 per cent, rising to 16 per cent if repair was combined with either renal or distal reconstruction ($P < 0·001$). Similar results were obtained with AFBG (3·4 and 11 per cent respectively, $P < 0·001$). The first major complication encountered was cardiac (39·8 per cent), followed by bleeding (20·5 per cent), respiratory (13·5), and gut (5·3 per cent), or limb ischaemia (6·4 per cent). Bleeding was commoner following reconstruction for aneurysm compared with that for occlusive disease ($P < 0·05$). Eighty-six patients (50·3 per cent) died from the first major complication. Of the remainder, 45 (53 per cent) developed multisystem organ failure (MSOF). The most commonly involved systems were cardiac, respiratory and renal.

Conclusion Cardiac problems were the major cause of death following infrarenal aortic reconstruction. MSOF is the 'final common pathway' in about half of the patients who survive the initial complication.

Patients with an abdominal aortic aneurysm (AAA) have a high prevalence of both symptomatic and asymptomatic cardiac disease[1]. Cardiac problems are frequent following aortic reconstruction. Major cardiac problems (cardiac death, myocardial infarction or left ventricular failure) have been reported in 15 per cent of patients undergoing aortic reconstruction[2]. Less serious cardiac events occur in 25 per cent. The incidence of silent postoperative ischaemic changes may be even higher[3]. A recent report[4] has challenged the view that cardiac events are the commonest cause of death following aortic reconstruction, suggesting that multisystem organ failure (MSOF) is the leading cause. If this is true, efforts to identify patients with cardiac disease before operation may be misplaced. Alternatively, perhaps cardiac risk factors are being successfully identified and modified before aortic reconstruction, although there is little evidence to support this hypothesis.

The aim of this paper was to define the incidence and cause of death in patients undergoing elective infrarenal aortic reconstruction.

Patients and methods

Data were collected from members of the Joint Vascular Research Group who had collected information prospectively on elective aortic reconstructions. In addition to demographic data, the nature and timing of the first significant adverse event during or after operation were noted. Subsequent progress of the patient was defined. Together with the number and details of patients who died, each surgeon provided the number of elective aortic reconstructions performed during the study interval.

The Detsky index was calculated as described previously[2]. Essentially this is a scoring system whereby points are ascribed to pre-existing risk factors. Coronary artery disease, left ventricular failure, valvular disease, arrhythmias, poor general condition and age over 70 years are all defined and scored. The greater the score, the more likely are postoperative cardiac events[5–7].

MSOF was diagnosed in the presence of failure of more than one of respiratory, renal, cardiovascular, coagulation, central nervous, gastrointestinal or immunological systems[8].

Results

Data were obtained from 20 surgeons, 14 of whom worked in a teaching hospital. Details on 3786 patients having elective aortic reconstruction were obtained. Of these, 171 died. Some 140 deaths (81·9 per cent) occurred during 1990–1995. The majority of patients were men; the median age of the group was 74 (range 48–87) years (*Table 1*). Twenty-five (18·8 per cent) of the 133 patients who had AAA repair and died were over 80 years of age. By contrast, 12 of the 38 patients who died following an aortofemoral bifurcation graft (AFBG) were younger than 65 years. In patients with aortic occlusive disease, the indication for operation was rest pain or ulceration in 25 and incapacitating claudication in the remainder. Aortic reconstruction was combined with other reconstructions in

Table 1 Details of 171 patients who died after elective aortic surgery

	Aortic aneurysm repair	Aortofemoral bypass graft	Total
Men	108	26	134
Women	25	12	37

Paper accepted 22 September 1997

24 patients who died (lower limb revascularization, 14; renal or visceral revascularization, ten).

The mortality rate following AAA repair, whether straight or bifurcated graft, was 4·8 per cent ($n = 2680$). By contrast, when aneurysm repair was combined with either distal or renal reconstruction, the mortality rate rose to 16 per cent of 96 patients ($\chi^2 = 22·3$, 1 d.f., $P < 0·0001$). Similar results were obtained with AFBG for occlusive disease. The mortality rate when AFBG alone was performed was 3·4 per cent in 940 patients. This compared with a mortality rate of 11 per cent in 80 patients who had AFBG combined with a further reconstruction ($\chi^2 = 11·5$, 1 d.f., $P < 0·001$). There was no difference in mortality rates in district general hospitals (DGHs) compared with teaching hospitals. The mortality rate following uncomplicated AAA repair in a DGH was 6·2 per cent of 786 cases, compared with 4·3 per cent of 1849 cases in a teaching hospital ($\chi^2 = 2·8$, 1 d.f., P not significant). Similar results were obtained for AFBG: 2·8 per cent of 177 cases in a DGH compared with 3·5 per cent of 753 cases in a teaching hospital ($\chi^2 = 0·28$, 1 d.f., P not significant).

First major complication encountered (Table 2)

A cardiac event was noted in 68 patients (39·8 per cent), most frequently myocardial infarction. Calculation of the Detsky index in patients sustaining a major cardiac event revealed a median score of 10 (range 0–40). Forty-five patients had a Detsky index of 10 or more. Pre-existing cardiac risk factors in this group of patients included angina (26 patients), myocardial infarction (22) and cardiac arrhythmia (three).

Intra-abdominal bleeding occurred in 32 of 133 patients who died following AAA repair compared with three of 38 after AFBG ($\chi^2 = 4·7$, 1 d.f., $P < 0·05$). Nine of these 35 patients died on the operating table.

Respiratory complications developed in 23 patients. Three patients had a pulmonary embolus and four an overwhelming chest infection. It was impossible to wean the remaining 16 patients off the ventilator. Two patients were initially successfully extubated but required reventilation for respiratory distress. Six of these 16 patients had severe chronic obstructive airway disease (COAD).

Table 2 First major complication encountered in patients who died after elective aortic surgery

Multisystem organ failure	45
Unclear	1

The first major complication occurred within 24 h of operation in 84 patients (49·1 per cent) and within 3 days in 134 (78·7 per cent). In 21 patients the event was intraoperative.

Outcome following initial complication

Eighty-six patients (50·3 per cent) died from the first complication. The remainder went on to develop further complications (*Table 3*). Forty-eight of the 68 patients who originally sustained a cardiac event died from that event. Only 37 of the 103 patients who presented initially with a non-cardiac complication died as a result of it ($\chi^2 = 19·6$, 1 d.f., $P < 0·001$).

Of the 85 patients who survived the first complication, 45 (53 per cent) developed MSOF (*Table 4*). The median number of systems involved was 3 (range 2–4).

Fifty patients required 59 reoperations: 22 had a laparotomy for bleeding, 20 a laparotomy for bowel ischaemia and 17 reoperation for limb ischaemia. Seven patients required a major amputation.

Death occurred within 24 h of operation in 22 patients (12·9 per cent) and within 2 days in 44 (25·7 per cent). The median interval between operation and death was 5 days. Most patients (121) died on the intensive therapy unit, 33 died on the surgical ward, ten in the operating theatre, two on a coronary care unit and five on a high-dependency unit.

Discussion

In the 1960s several reports showed that the mortality rate following elective AAA repair was approximately 10 per cent[9,10]. Over the next two decades, with improvements in

Table 4 Multisystem organ failure as the cause of death: systems involved

	No. of patients

surgical, anaesthetic and intensive care techniques, the rate fell to 5 per cent or less, and in some series was down to zero[11]. Results described here are similar to those in other reports. The mortality rate following elective aortic reconstruction may rise over the next few years as the more technically straightforward cases of both occlusive and aneurysmal disease are dealt with successfully by interventional radiology[12].

Combining aortic reconstruction with either renal or distal revascularization significantly increases mortality. Similarly, Bickerstaff *et al.*[13] found that combining AAA repair with a further procedure, whether vascular or non-vascular, almost doubled the mortality rate following AAA repair alone. Another report[14] described a mortality rate of approximately 10 per cent when aortic reconstruction was combined with renal or superior mesenteric artery revascularization. Huber *et al.*[4] reported a mortality rate of 9 per cent for renal plus aortic reconstruction and 16 per cent for aortic reconstruction and revascularization of the leg.

In the present series there was no difference in mortality rates between operations performed in a teaching or district general hospital. Some studies have suggested a higher mortality rate in a DGH[15]. On the other hand, there are reports of aneurysm repair carried out in DGHs with low mortality rates[16]. The important factors in determining mortality are likely to be the enthusiasm and training of the surgeon involved and the number of cases undertaken. Amundsen *et al.*[17], in a series of 279 elective AAA repairs, found a significantly lower mortality rate reported by surgeons who carried out more than ten repairs per year. Mortality rate did not depend on the type of operation or the size of hospital.

This study confirms that cardiac problems are the commonest cause of death. Patients who initially sustain a cardiac complication are more likely to die from that problem than those who suffer other primary complications. In a large multicentre study, Johnston[18] found that two-thirds of deaths following repair of non-ruptured AAA were due to cardiac complications. The study also showed that patients who had a cardiac problem after operation had a 25 per cent mortality rate compared with 1 per cent in those with no cardiac complications. In addition to the features described by Detsky, a history of transient ischaemic attacks[19] and electrocardiographic changes suggesting ischaemia[17] are also risk factors for cardiac morbidity and mortality.

A number of methods are available to identify patients at high cardiac risk. The commonest method used in the UK was found to be measurement of cardiac ejection fraction[20]. Surgeons who carry out a greater number of vascular procedures were more likely to assess preoperative cardiac risk. The Detsky index is useful in identifying high-risk patients. A score of 10 or more is significantly associated with cardiac morbidity and mortality[5,6]. In this series two-thirds of patients who developed a serious cardiac event had a score of 10 or more.

Bleeding was the cause of death in 20·5 per cent of patients. Serious intraoperative bleeding occurs in approximately 5 per cent of AAA repairs. In half of these patients bleeding arises from the anastomosis or from vascular clamp damage. In the remainder the bleeding comes from major veins[18]. Complications associated with significant intraoperative bleeding include coagulopathy, new cardiac arrhythmias, prolonged ventilation and impaired renal function.

Postoperative chest infection is the commonest cause of morbidity after AAA repair[21]. COAD is a recognized risk factor for mortality[18]. In this series one-third of patients with respiratory failure had severe pre-existing COAD.

Rather than being the cause of death, in the present study MSOF was the 'final common pathway' in the majority of patients who survived the initial complication. Cardiac complications continue to be the main precipitating factor accounting for death after elective aortic reconstruction.

Survey of changes in the provision of vascular surgical services in the Oxford Region over 5 years

R. B. GALLAND and T. R. MAGEE

Department of Surgery, Royal Berkshire Hospital, London Road, Reading RG1 5AN, UK
Correspondence to: Mr R. B. Galland

Aim This study aimed to examine changes in the provision of vascular services in the Oxford region over 5 years.

Methods A questionnaire was sent to all general surgeons in the region asking of their involvement in vascular surgery. Data were obtained from the Department of Health concerning vascular procedures and inpatient codes for each district in the Oxford Region from 1990–1991 to 1994–1995. Office of Population Censuses and Surveys (OPCS) data for abdominal aortic aneurysm repair and femoral artery reconstruction were validated against data collected prospectively for West Berkshire.

Results Eighteen of 45 surgeons who replied to the questionnaire carried out elective and emergency arterial work. All were members of the Vascular Surgical Society of Great Britain and Ireland (VSS). All but one took part in the general surgical rota. Eight surgeons carried out emergency arterial surgery only; only two of these were members of the VSS. Of 19 surgeons undertaking no arterial surgery, 15 operated on primary and 11 on recurrent varicose veins. The number of arterial reconstructions rose from 20·8 per 100 000 population to 28 per 100 000 throughout the study. The greatest increase occurred in districts where a new vascular consultant had been appointed. Similar results were obtained with endovascular procedures. The number of major amputations remained fairly constant at approximately 11 per 100 000 population. The number of inpatient episodes for arterial disease also rose, from 35·7 to 47·6 per 100 000. In validating OPCS codes against prospectively collected data, discrepancies for individual years were noted but the annual trend was reflected fairly accurately by the codes.

Conclusion There has been an increase in vascular activity in the region, but variations still exist between different districts.

The UK is lagging behind Europe in the identification of vascular surgery as a separate subspecialty. A questionnaire survey in 1988 showed that in ten of 21 European countries vascular surgery was separate from both general and cardiothoracic surgery[1]. A survey published in 1992 showed that only 4 per cent of members of the Vascular Surgical Society of Great Britain and Ireland (VSS) were pure vascular surgeons[2].

Nevertheless the general surgical component of vascular and general surgery in the UK is diminishing as vascular surgery expands[3]. This separation is being maintained by the creation of new vascular consultant posts[4].

In a previous report marked differences were identified between hospitals in the Oxford Region in the number of patients admitted with the diagnosis of peripheral vascular disease[5]. A considerable variation was also identified in the number of vascular reconstructions and amputations done. Centres with high rates of distal arterial reconstructions did fewer major amputations. The amputations were likely to be carried out more distally and to have been preceded by a surgical attempt to save the limb[6].

The aim of this study was to determine how the provision of vascular surgery has changed in the Oxford Region over 5 years.

Patients and methods

In 1994 Oxford Region combined with East Anglia to form the Anglia and Oxford Regional Health Authority. This study examines changes in the old Oxford Region between 1990 and 1997. Oxford Region has a population of about 2·5 million. There are eight districts serving populations of 150 000 to 500 000. There is one teaching hospital in the region.

A questionnaire was sent, in February 1997, to each surgeon in the region known to be practising general and/or vascular surgery, asking about involvement in vascular surgery. This was compared with a similar questionnaire from 1992[5].

Data were obtained for inpatient episodes and operations relating to arterial surgery in the Oxford Region. The source for this information was the Department of Health, being based on district statistical returns. Data were obtained for the 5 years from 1990–1991 to 1994–1995. The latter represented the most up-to-date information available. International Classification of Diseases, 9th revision (ICD9) codes obtained were: 441.3–6, 442.0–3, 442.8, 442.9, 444.0–2, 444.8 and 444.9. Office of Population Censuses and Surveys (OPCS) codes relating to vascular procedures and amputations obtained were: L18–20, L29, L34, L37, L41, L45, L48–52, L56–59, L65 and X09. Numbers of patients undergoing iliac (L54.1) and femoral (L63.1) percutaneous transluminal angioplasty (PTA) were also obtained.

Data for West Berkshire District Health Authority were validated against data collected prospectively from the Royal Berkshire Hospital for abdominal aortic aneurysm (AAA) repair (L18, L19) and bypass operations on the femoral artery (L59).

Results

Between 1992 and 1997 six general surgeons with a vascular interest were appointed in the region. Only one of these was to replace a retiring consultant.

Questionnaire study

In the first questionnaire 40 replies were received from 45 surgeons surveyed[5]. In the present study 45 replies were

---

Paper accepted 21 October 1997

received from 47 surgeons. Eighteen surgeons presently carry out emergency and elective arterial surgery, eight do emergency operations only and 19 perform no arterial surgery. These values are similar to those obtained in 1992 (16, 11 and 13 respectively). All the surgeons who carry out emergency and elective arterial work are members of the VSS. In addition to covering vascular surgery, all but one of these 18 surgeons also took part in the general surgical rota. Only two of the eight carrying out emergencies only are members of the VSS. Of 19 surgeons carrying out no arterial surgery 15 undertook primary and 11 recurrent varicose vein operations. Seven of these 19 surgeons stated that they would allow an appropriately trained junior surgeon to carry out an emergency thromboembolectomy under their care. Only one would allow a ruptured aneurysm to be so treated.

Vascular reconstructions

In 1990–1991, 524 operations were carried out in the Oxford Region. This represents approximately 20·8 operations per 100 000 population. By 1994–1995 the number of operations had risen to 701, equivalent to 28 per 100 000 population. *Fig. 1* shows the changes in operations performed for each of the eight districts for 1990–1991 compared with 1994–1995. Excluding the two districts carrying out few reconstructions, the range in the remaining six was 9·2–34·9 in 1990–1991 and 19·1–46·5 in 1994–1995. Each of the three districts to which a new consultant vascular surgeon had been appointed showed an increase in the number of operations done (*Fig. 2*). The mean number of operations in the three districts rose from 14·3 to 28·9 per 100 000. This represents a rise of 102 per cent. In the other five districts there was only a 5 per cent increase in activity (19·2 per 100 000 rising to 20·2 per 100 000).

Amputations

Approximately 11 per 100 000 population major (X09) and minor (X10, X11) lower limb amputations were carried out in the region per year (*Fig. 3*). These figures include amputations for trauma, deformity and malignancy in addition to those carried out for vascular disease. There is not likely to have been any significant change in the first three indications. Of patients referred to the Oxford Region prosthetic service, an original diagnosis of vascular disease (including diabetes) was made in 67 per cent in 1990 compared with 64 per cent in 1996 (J. D. Morrison, personal communication 1997). There appears to be no decrease in the number of amputations despite the increased vascular workload.

Inpatient episodes

Examination of ICD9 codes showed 893 (equivalent to 35·7 per 100 000) inpatient episodes in 1991. By 1994–1995 this had risen to 1190 (47·6 per 100 000), an increase of 33 per cent. The overall increase was greatest in the three districts with a new vascular appointee (50 per cent increase compared with 21 per cent in the other five districts).

Endovascular procedures

The number of iliac and femoral angioplasties performed in the region rose from 8·2 per 100 000 in 1990–1991 to 21·7 per 100 000 in 1994–1995. Excluding two districts that reported no procedures in 1994–1995, the range of procedures in the remaining six districts was 0·7–17·0 in 1990–1991 and 8·1–34·3 in 1994–1995. The three districts in which a new vascular surgeon was appointed showed an

increase of 312 per cent. The increase in the remaining five districts was 268 per cent.

Validation of Office of Population Censuses and Surveys codes compared with prospective audit

There was a close correlation for OPCS codes recorded in West Berkshire compared with the number of aortic aneurysms repaired in the Royal Berkshire Hospital (*Fig. 4*). Some of the variation seen between emergency and elective operations is likely to be due to the fact that acute (non-ruptured) AAAs are not coded separately[7]. Inevitably, therefore, some of these will be included as elective and some as emergency operations. Code L59 is designated 'other bypass of femoral artery'. It includes femorofemoral, femoropopliteal and distal bypass and 'non-specified procedure'. Given the heterogeneous nature of this group it is not surprising that there is more variation when comparing codes with audit. However, the trend showing annual numbers of procedures performed is reflected by the coding (*Fig. 5*).

Discussion

ICD and OPCS codes represent a form of statistical analysis of diseases and procedures. Their function is to facilitate the management of healthcare services[8]. They can be regarded as representing an intermediate category between Read codes (comprising clinical terms used most commonly) and Healthcare Resource Group and Health Benefit Groups[9].

ICD and OPCS codes produced by Hospital Activity Analysis have been shown to be up to 20 per cent inaccurate[10]. Furthermore, discrepancies have been identified in the defined codes obtained by different individuals[11]. The present results confirm discrepancies between recorded OPCS codes and data collected prospectively when data are analysed for individual years. However, the trend for change over the 5 years of the study is represented fairly accurately by the coding system (*Figs 4* and *5*).

Analysis of both procedure codes and inpatient episodes for vascular surgery shows an increase in activity over 5 years. These increases were most pronounced for districts in which new vascular surgeons had been appointed. This confirms the findings of others, based on locally collected data, which show increases in vascular activity following both new and replacement consultant vascular appointments[3,12]. The increase in vascular reconstruction and PTA in the region was not associated with any decrease in the number of major amputations, although it has been reported to have reduced the number of amputations in one district of the Oxford Region[13]. Other studies have shown that amputation rates fall as rates of vascular reconstruction and angioplasty rise[6,14]. On the other hand, a large study from Maryland, over 10 years, showed significant increases in the numbers of PTAs and peripheral bypass operations carried out whilst the number of major amputations remained constant[15]. A report from Scotland showed that areas of the country with a high rate of vascular reconstruction had a correspondingly high rate of major amputation[16]. Increasing numbers of vascular reconstructions have, however, been shown to result in an increase in the age of patients having an amputation[17]. It needs to be remembered that not all patients will have a vascular reconstruction for critical ischaemia. Pell *et al.*[16] demonstrated an increase in the number of admissions for patients with peripheral vascular disease, but the number with gangrene who were admitted remained constant. Natural history studies have shown that patients with intermittent claudication have a low risk of developing rest pain or gangrene[18]. However, the quality of life of patients with claudication can be improved by revascularization[19], at least in the short term[20].

The rate of major amputation in the Oxford Region is lower, at approximately 11 per 100000 population, than reported elsewhere. For example, rates of 30 per 100000 have been reported in Denmark[21,22] and 20 per 100000 in Finland[23]. This is not surprising as different rates of atherosclerosis occur in different populations. In Oxfordshire the prevalence of atherosclerosis in a population sample was 2·2 per cent[24]. Values from similar populations in Denmark and rural Finland were 5·8 and 7·7 per cent respectively.

Despite the overall increase in vascular activity across the region, variations in the number of procedures being carried out in different districts are still apparent. Individual surgical units[25] and nationally collected data[26] have shown a steady increase in vascular activity over the past 20 years. Eickhoff *et al.*[27] provided data from the Danish National Patient Register. A statistically significant variation in vascular operations performed in different counties in Denmark was identified. The range of ratios of observed to expected reconstructions was 0·61–1·54.

There is evidence that the general surgical component of a general and vascular surgical firm is falling[3,26]. The majority of vascular surgeons in Oxford Region continue to take part in general surgical emergency cover. It is clear that operations on varicose veins are still regarded as part of general surgery. The majority of surgeons carrying out no arterial operations still dealt with varicose veins, and over half operated on recurrent veins. However, a questionnaire sent by the VSS to members and non-members in 1995 confirmed that, although non-vascular surgeons were carrying out varicose vein operations, they were doing proportionately fewer than in 1992.

Role of magnetic resonance angiography for assessment of abdominal aortic aneurysm before endoluminal repair

A. NASIM, M. M. THOMPSON, R. D. SAYERS, J. R. BOYLE, T. HARTSHORNE, A. R. MOODY* and P. R. F. BELL

*Departments of Surgery and *Radiology, Clinical Sciences Building, Leicester Royal Infirmary NHS Trust, Leicester LE2 7LX, UK*
Correspondence to: Mr A. Nasim

Background A detailed knowledge of the morphology of the aorta and iliac arteries is an important prerequisite for successful endoluminal abdominal aortic aneurysm (AAA) repair. The best method of preoperative evaluation remains to be determined.

Methods A prospective study was undertaken between January 1994 and July 1995 to assess the ability of computed tomography (CT), magnetic resonance angiography (MRA), colour duplex imaging and intra-arterial digital subtraction angiography (IA-DSA) to visualize AAA morphology.

Results Eighty-two consecutive patients (64 men, 18 women) with AAA were assessed with MRA, contrast-enhanced CT, colour duplex imaging and IA-DSA. Median age was 74 (range 59–87) years and median AAA diameter was 5·7 (range 3·5–9·7) cm. Five patients were unable to tolerate CT or MRA examination. Seventy-seven patients underwent both CT and MRA. Of these, 55 also had a colour duplex scan and 32 underwent arteriography. The scans were assessed by an independent blinded observer. MRA was significantly better ($P < 0·01$) at visualizing AAA morphology compared with CT and colour duplex imaging. There was no statistically significant difference between MRA and arteriography.

Conclusion MRA is useful in patient selection for endoluminal AAA repair, as it avoids use of iodinated contrast medium and ionizing radiation.

For conventional open repair of abdominal aortic aneurysms (AAAs), ultrasonography alone may be adequate for preoperative assessment. Contrast-enhanced computed tomography (CT) or arteriography may be performed if renal artery involvement or associated distal arterial occlusive disease is suspected[1]. Endoluminal AAA repair, however, requires a more detailed assessment of the abdominal aorta for determining patient suitability and accurate sizing of the intraluminal prosthesis[2].

Neither CT nor arteriography is completely reliable in predicting the proximal or distal extent of AAA[3,4]. Some of the drawbacks can be overcome with spiral CT[5], although the problems of X-ray exposure and injection of iodinated contrast media persist. A major drawback of angiography is that, in the presence of mural thrombus, the external extent of the AAA sac is not visualized.

Recent studies using magnetic resonance angiography (MRA) suggest that this may be a better tool for assessing AAA morphology[6–8] than conventional cross-sectional imaging. Previously spin-echo magnetic resonance imaging (MRI) provided only limited detail of the aortic branch vessel anatomy. However, the development of MRA using gradient echo techniques combined with contrast enhancement (*Fig. 1*) has overcome many of these limitations[8,9].

In this study an assessment was made of the ability of CT, MRA, colour duplex imaging and intra-arterial digital subtraction angiography (IA-DSA) to visualize AAA morphology.

Patients and methods

Patients with asymptomatic AAAs referred to Leicester Royal Infirmary between January 1994 and July 1995 underwent assessment with MRA, contrast-enhanced CT and colour duplex imaging. Those with favourable anatomy for endoluminal repair on the basis of these three non-invasive imaging modalities underwent further assessment with IA-DSA. The ability of each test to visualize the following parameters was determined: right and left renal artery origin, proximal aneurysmal neck length, maximum anteroposterior diameter, tortuosity of aneurysm sac,

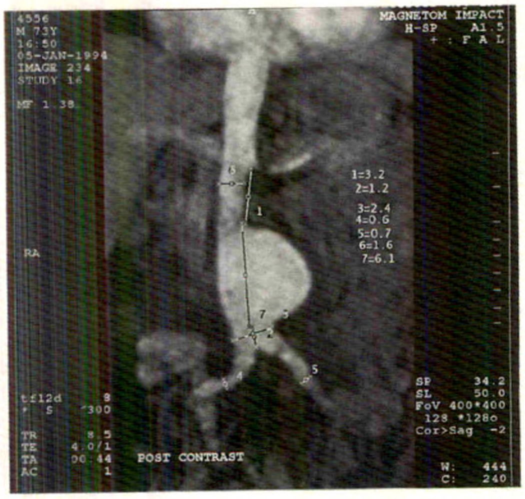

Fig. 1 Image of the abdominal aorta obtained using magnetic resonance angiography (gradient echo sequence), demonstrating the origin of the renal arteries, the infrarenal abdominal aortic aneurysm and tortuosity of the iliac arteries

---

Based on a previous communication to the Vascular Surgical Society of Great Britain and Ireland, (London, UK, November 1995), and published in abstract form as *Br J Surg* 1996; 83: 559
Paper accepted 25 September 1997

distal neck length, tortuosity of iliac arteries and iliac artery diameter. The proximal neck was defined as the non-aneurysmal segment of aorta (less than 30 mm) between the origin of the lowest renal artery and the start of the aneurysm (aortic diameter greater than 30 mm), and the distal neck was defined as the length of non-aneurysmal segment before the aortic bifurcation.

Magnetic resonance angiography

All scans were performed on a Siemens (Erlangen, Germany) IT scanner employing 10mT/m gradients and a 50-cm body coil. A rapid magnetization prepared two-dimensional, gradient echo multiplanar sequence (TurboFLASH-time to repetition 8.5, echo time 4, inversion time 300, flip angle 8, 128 × 128, field of view 400 × 400, 8 mm thick) was used. Four discrete blocks of slices were positioned to acquire images directly in the coronal and sagittal planes and obliquely along the line of the renal arteries. Contrast enhancement was achieved using intravenous injection of 15 ml of gadolinium diethylenetriamine penta-acetate (Magnevist; Schering, Burgess Hill, UK) diluted to 30 ml with normal saline. The contrast injection was timed to allow a precontrast measurement, one during the arterial phase, one in the venous phase and a final steady-state measurement. All scans were obtained during quiet respiration. The total scanning time was 3 min. Images were viewed either from the source images or were postprocessed using maximum intensity projection to create angiographic type images in each of the four planes: coronal, sagittal and two paraoblique. Postprocessing on average took 20–30 min.

Computed tomography

CT was performed using a Siemens HiQ scanner. Contiguous slices of 10 mm thickness were obtained from the diaphragm inferiorly. On reaching the renal vessels 3-mm slices were used, and a similar scanning technique was employed through the region of the aortic bifurcation. The intervening aorta was scanned with 10-mm slices. Some 100 ml of contrast (Omnipaque 320; Nycomed, Birmingham, UK) was hand-injected at approximately 2 ml/s when scanning from the level of the renal vessels, which was performed dynamically in quiet respiration and commenced after a 40-s delay.

Colour duplex imaging

Colour duplex examinations were performed with an Advanced Technology Laboratories Ultramark-9 HDI colour scanner (Advanced Technologies, Washington, DC, USA). All examinations were performed by an experienced vascular technician using a colour Doppler imaging frequency of 3·0 MHz and a pulsed Doppler frequency of 2·5 MHz.

Intra-arterial digital subtraction angiography

IA-DSA was performed by percutaneous catheterization of the femoral artery using the Seldinger technique. A marker pigtail catheter with eight side-holes (6 Fr, 65 cm long; Cordis, Miami, Florida, USA) was used. Some 80 ml of contrast (Omnipaque 300; Nycomed) were injected at 20 ml/s. Anteroposterior and lateral views of the abdominal aorta, and anteroposterior and oblique views of the iliac arteries, were obtained with a Siemens Multiskop equipped with a Digitron computer system (Siemens).

Results

A total of 82 patients was assessed. There were 64 men and 18 women of median age 74 (range 59–87) years. Median AAA diameter was 5·7 (range 3·5–9·7) cm. Five patients did not tolerate CT ($n = 1$) or MRA ($n = 4$) and were excluded from analysis.

Table 1 Comparison of aneurysm morphology visualized by each investigation

Parameter	CT	MRA	Colour duplex	IA-DSA
Right renal artery	64	91	51	100
Left renal artery	78	97	51	100
Proximal neck length	80*	95	51	78
Maximum anteroposterior diameter	100	100	98	6
AAA sac tortuosity	0	100	94	97
Distal neck length	92	99	94	59
Tortuosity of iliacs	0	91	85	100
Diameter of iliac arteries	91	84	78	100

Values are the percentage of patients in whom each parameter was visualized adequately. *In some patients this measurement was inferred from visualization of a single renal artery origin. AAA, abdominal aortic aneurysm; CT, computed tomography; MRA, magnetic resonance angiography; IA-DSA, intra-arterial digital subtraction angiography

Comparison of imaging techniques

Seventy-seven patients successfully underwent both CT and MRA. Of these, 55 also had a colour duplex scan and 32 proceeded to IA-DSA. The scans were assessed by an independent blinded observer. The results are presented as the percentage of patients in whom the above parameters could be assessed adequately by each investigation (*Table 1*).

Visualization was considered to be adequate if six or more parameters (from a maximum of eight) were identifiable. Statistical analysis using the χ^2 test showed MRA (95 per cent adequate) to be significantly better ($P<0{\cdot}01$) at visualizing AAA morphology than CT (50 per cent) and colour duplex imaging (45 per cent). There was no statistically significant difference between MRA and IA-DSA (95 *versus* 85 per cent respectively).

Aortic aneurysm morphology

On the basis of the above results, MRA images in 78 patients were used to study AAA morphology and to determine suitability for endoluminal repair. Four distinct morphological groups were identified when applying the current criteria for endoluminal repair (*Table 2*): group 1 – aneurysms with a sufficient proximal and distal neck ($n = 21$); group 2 – aneurysms with a sufficient proximal

Table 2 Anatomical criteria used currently for endoluminal abdominal aortic aneurysm repair with tube and bifurcated grafts

	Tube	Bifurcated
Proximal neck length (mm)	15	15
Proximal neck diameter (mm)	<28	<28
Distal neck length (mm)	10	0
Iliac artery diameter (mm)		
Minimum	8	8
Maximum	—	14

Severe aneurysm and iliac artery tortuosity (change in direction greater than 60°) also contraindicate endoluminal repair

Table 3 Reasons for unsuitability for endovascular abdominal aortic aneurysm repair

	No. of patients ($n = 78$)
Group 1 ($n = 21$)	
Suitable for tube or straight graft	12 (15)
Unacceptable proximal neck or iliac angulation	4 (5)
Distal neck stenosis	1 (1)
Isolated iliac aneurysms	3 (4)
Proximal neck diameter greater than 28 mm	1 (1)
Group 2 ($n = 37$)	
Suitable for bifurcated graft endoluminal repair	16 (21)
Proximal neck diameter greater than 28 mm	2 (3)
Iliac artery stenosis less than 7 mm	2 (3)
Unacceptable proximal neck or iliac angulation	5 (6)
Extension of aneurysm to internal iliac artery (greater than 14 mm)*	12 (15)
Group 3 ($n = 14$)	
Insufficient proximal neck length (less than 15 mm)	14 (18)
Group 4 ($n = 6$)	
Pararenal or suprarenal aneurysm	6 (8)

Values in parentheses are percentages. *May be treated with an aortouni-iliac graft in combination with femorofemoral crossover bypass

neck but insufficient distal neck or iliac involvement ($n = 37$); group 3 – infrarenal aneurysms with insufficient proximal neck ($n = 14$); and group 4 – aneurysms with pararenal or suprarenal extension ($n = 6$).

Overall only 28 patients (36 per cent) met the criteria for endovascular repair. Of the 21 patients in group 1, only 12 were suitable for a straight or tube graft. A further three patients from group 1 could be treated with a tube graft in combination with endoluminal repair of an isolated common iliac aneurysm. Of the 37 patients in group 2, only 16 met the criteria for a bifurcated endoluminal graft. *Table 3* lists the reasons for excluding other patients from endoluminal repair. There was no significant correlation between the size of the aneurysm and the length of the proximal and distal necks.

Discussion

Vascular imaging plays a vital role in determining patient suitability for endoluminal AAA repair and in the selection of an appropriate endovascular device[10,11]. Although conventional CT remains useful in prediction of AAA size and detection of other retroperitoneal pathology[12], it has several drawbacks. The visceral and renal artery origins are often not visualized, as they may fall between slices, and have to be inferred from the surrounding anatomy[13]. Conventional CT images are obtained along the axial plane of the body which does not conform to the plane of the aortoiliac segment as it is often angulated and tortuous in patients with AAA. This produces oblique images of the aorta making interpretation of visceral artery origins difficult. It is not possible to obtain assessment of the proximal neck length in these cases, which is an important factor in determining patient suitability for endoluminal repair. In this study there was inadequate visualization of both renal artery origins in up to 40 per cent of patients. Visualization of the renal arteries was considered adequate only if their origin from the aorta was seen clearly on a scanning plane. Adherence to this strict criterion may account for the above poor results. Conventional CT also results in potential inaccuracies in assessment of the aneurysmal sac length and tortuosity of the aortoiliac segment.

Colour duplex scanning has been proposed previously as the modality of choice for preoperative assessment of AAA for endoluminal repair[14]. In this centre, although colour duplex is regarded as a 'gold standard' for assessment of lower limb arterial lesions[15], it is not as useful in the assessment of AAA. It provided excellent assessment of the distal extent of the aneurysm and of the iliac artery morphology but in around 50 per cent of patients visualization of the renal artery origins was obscured by the presence of bowel gas or obesity. Duplex imaging is, however, very operator dependent and therefore results may vary between centres[14].

Arteriography is very useful in demonstrating visceral artery origins and for assessing the state of the distal vessels[16,17]. However, in the presence of mural thrombus, the proximal and distal limits of the aneurysm sac are obscured, and the normal calibre of the lumen may be mistaken for normal aorta, with overestimation of the proximal and distal neck lengths. Another important limitation of aortography is that of magnification error. This may partially be overcome by use of a calibrated angiographic catheter (as described above) but accurate assessment of arterial diameters is still difficult.

MRA has evolved to become an accepted non-invasive method of imaging arteries[18–21]. MRA uses gradient echo techniques to create angiographic type images which may be acquired using two-or three-dimensional techniques. It is not affected by bowel gas and can outline the size of the lumen as well as the thrombus thickness without the use of iodinated contrast medium. The disadvantages of MRA are relatively few. A small proportion of patients experience claustrophobic symptoms and may not tolerate the examination (5 per cent in this study). MRA is also contraindicated in patients with pacemakers or intracranial metal clips. The entire examination can be completed in 20–30 min. Image quality and scan acquisition times continue to be improved by technical advances such as improved gradient strengths and local coil design. In conjunction with bolus-technique contrast enhancement, this results in high-resolution, high-contrast, relatively artefact-free angiographic type images. In the present study MRA provided the best non-invasive assessment of the AAA parameters relevant to patient selection and graft sizing for endoluminal repair.

In this study only 36 per cent of patients could be treated endoluminally with the currently available tube and bifurcated devices, consistent with other series[5,22,23]. A tapered aortouni-iliac graft with occlusion of the contralateral common iliac artery and an extra-anatomic crossover graft can be used when the iliac vessels are wide (greater than 14 mm) or aneurysmal. This device is, therefore, applicable in a higher proportion of patients but doubts remain about the long-term patency of the extra-anatomic bypass[24]. A significant proportion of patients continue to require conventional open repair.

MRA could have a role in patient selection for endoluminal repair and can produce the same information as combined CT and aortography but without the use of iodinated contrast medium, ionizing radiation or arterial puncture. Conventional angiography can, therefore, be reserved for patients who require distal artery imaging.

Background This study reviews the results of infrarenal abdominal aortic aneurysm (AAA) surgery over 21 years (1 January 1976 to 31 December 1996).

Methods A prospectively gathered database was analysed.

Results Infrarenal AAA repair was performed in 1515 patients: 492 (32·5 per cent) had elective repair of an asymptomatic AAA; 194 (12·8 per cent) had elective repair of a symptomatic AAA; 156 (10·3 per cent) had emergency repair of a symptomatic non-ruptured AAA; and 673 (44·4 per cent) had surgery for a ruptured AAA. The 30-day and/or same admission mortality rates were 6·1, 5·8, 14·1 and 37 per cent respectively. Operative mortality increased in all four groups over the study interval, although this only attained statistical significance in patients having elective repair of a symptomatic, non-ruptured AAA. There was a significant increase in the age of patients undergoing elective repair of an asymptomatic AAA, but not in the other three groups. There was also a significant increase in the proportion of straight 'tube' grafts inserted in all four groups.

Conclusions It remains the minority of patients who have elective operation before the onset of symptoms and/or rupture. Despite anaesthetic and surgical specialization, the results of AAA repair have not improved over the past two decades. Operative mortality may be increasing, possibly because of the increasing age and associated comorbidity of the patients presenting to this unit.

In the UK, infrarenal abdominal aortic aneurysm (AAA) more than 4·0 cm in diameter occurs in 2·3 per cent of men aged 65–74 years, and is estimated to be responsible for death in 1·7 per cent[1]. The number of patients with AAA presenting to vascular surgeons is increasing because of the growing awareness of the condition, more widespread use of abdominal imaging, ageing of the population and, possibly, increasing prevalence of the condition[2,3].

Operative series published from North America and Australasia suggest that the mortality rate associated with elective AAA repair is falling, and may even approach zero[4–6]. National[7] and local[8] audit data suggest that this is not the case in most UK hospitals and that elective mortality may, not infrequently, approach double figures[9].

By contrast, most accept that the mortality associated with repair of a ruptured AAA has failed to improve. Aneurysms at significant risk of rupture should therefore be identified and repaired wherever possible. In the UK, the number of asymptomatic AAAs currently detected and repaired is too small to affect significantly the overall community mortality from rupture. Whereas in the USA the ratio of elective to emergency repairs is increasing[10] and may be as high as 10:1, in the UK the reported ratio is often less than 2:1 and shows no sign of increasing[11,12]. The current management of AAA in the UK may be far from satisfactory, and is perhaps failing to improve in line with other countries where healthcare resources are more plentiful. The aim of the present study was to review the pattern of presentation and the results of AAA surgery in this unit over 21 years to determine whether any progress had been made in the management of this condition.

Patients and methods

A prospectively gathered database containing demographic, clinical, operative and outcome data on all patients who had surgery for infrarenal AAA in Edinburgh Royal Infirmary between 1 January 1976 and 31 December 1996 was analysed. Operative mortality was defined as death within 30 days of surgery or during the same admission as the operation. A patient was deemed to have undergone an AAA operation if he or she had received an anaesthetic with the intention of repairing the AAA, whether a graft was successfully inserted or not. Patients treated without surgery are not reported in this series. Data from 1976 to 1982 represent the work of three consultants with a special interest in vascular surgery who combined formally to create the Edinburgh Regional Vascular Surgery Unit in 1983. Throughout most of the study the unit has been staffed by three consultants, a fourth was appointed in October 1996. The population served in southeast Scotland approaches 1·2 million and has remained relatively constant during the study.

Results

A total of 1515 patients had surgery for an infrarenal AAA: 492 (32·5 per cent) had elective repair of an asymptomatic AAA; 194 (12·8 per cent) had elective operation for a symptomatic non-ruptured AAA; 156 (10·3 per cent) had emergency surgery for a symptomatic non-ruptured AAA; and 673 (44·4 per cent) had surgery for a ruptured AAA (*Fig. 1*). The operative mortality rates were 6·1, 5·8, 14·1 and 37·0 per cent respectively.

The proportion of patients who had elective repair did not significantly increase during the study. The male:female ratio did not change significantly during the study in any clinical group. Patients who had repair of a ruptured AAA were less likely to be female (119 of 673, 17·7 per cent) than those who had repair of a non-ruptured AAA (190 of 842, 22·6 per cent) ($P = 0{\cdot}02$,

Fisher's exact test). The sex ratio was not significantly different between the three non-rupture groups.

Operative mortality increased in all groups, but this only attained statistical significance in patients who had elective surgery for a symptomatic, non-ruptured AAA ($P<0{\cdot}008$, χ^2 test) (*Fig. 2*). There was a significant increase in the proportion of tube grafts inserted in all groups ($P<0{\cdot}01$, χ^2 test) (*Fig. 3*). Mortality was lower in patients who had repair with a tube graft (119 of 767, 15·5 per cent) compared with a bifurcated graft (118 of 648, 18·2 per cent), although this difference did not attain statistical significance. Sixty-seven patients with a ruptured aneurysm did not have a graft inserted successfully and all died in the operating theatre. There was a tendency for women having an aneurysm repair to be older than men, although this only attained statistical significance in patients with a ruptured aneurysm ($P<0{\cdot}04$, Mann–Whitney U test). In all groups, median age of the patients increased over the study interval, but this difference was significant only in those who had elective repair of an asymptomatic AAA ($P<0{\cdot}001$, χ^2 test) (*Table 1*). There was no significant association between age and outcome in patients undergoing repair of a non-ruptured AAA. However, in patients with a ruptured AAA 158 of 376 (42·0 per cent) aged over 70 years died compared with 91

Values are median (range) (interquartile range)

of 297 (30·6 per cent) aged 70 years or less ($P = 0{\cdot}003$, Fisher's exact test).

Discussion

The first principal finding is that, despite increasing surgical and anaesthetic specialization and experience, there has been no measurable improvement in the outcome of surgery for AAA over the past two decades, regardless of indication or degree of urgency. Indeed, operative mortality has tended to increase. Disappointingly, it is still the case that only a minority of patients in Edinburgh have elective surgery before the onset of symptoms and/or rupture. Although the pressure to publish only good or improving results must not be forgotten[13], the Edinburgh experience may reflect UK practice and appears to differ significantly from that reported in other developed countries. The results of any operative series depend crucially upon case mix. Published reports cannot be compared directly unless they contain detailed information with regard to catchment area and population, referral patterns, selection policies, patient risk factors, and the proportion and characteristics of patients refused operative repair. These in turn are difficult to define with precision and almost inevitably change over time. In the present series, there was a tendency for mean patient age to increase with time in all clinical groups, although this only attained statistical significance in patients having elective repair of an asymptomatic AAA. It is the clinical impression that the number of patients referred with large, surgically unfavourable AAA, and significant multisystem comorbidity, has increased markedly in recent years. At the same time, a recent local audit has indicated that a significantly greater proportion of referred patients with aneurysm rupture are accepted for surgery than was the case 5–10 years ago[12]. Despite deteriorating access to high dependency and intensive care beds locally it is becoming more difficult to turn down high-risk patients for either elective or emergency aneurysm repair, often due to pressure from families or medical colleagues. Although these factors may, at least in part, explain why the overall operative mortality has not decreased, it is difficult to prove. The fact that there has been a tenfold increase in AAA workload with little increase in resources and none in personnel may be equally relevant. Unless in future, patients are identified at an earlier stage, surgeons are unlikely to make a significant impact on overall community mortality from aneurysmal disease.

Population-based record linkage study of the incidence of abdominal aortic aneurysm in Western Australia in 1985–1994

J. B. SEMMENS, P. E. NORMAN*, M. M. D. LAWRENCE-BROWN†, A. J. BASS and C. D. J. HOLMAN

Background The incidence of abdominal aortic aneurysm (AAA) has increased steadily during the past 30 years.

Methods Trends in the incidence and surgical intervention for AAA in Western Australia were reviewed for the interval 1985–1994. A population-based health database was used to link morbidity and mortality records of all patients aged 55 years or more who died from rupture or were admitted and treated surgically for AAA. Three groups were separated for analysis: patients with a ruptured AAA, those admitted for elective repair and those admitted as an emergency with an acute (non-ruptured) aneurysm.

Results There was a decline in the incidence of both emergency and elective procedures for AAA after 1992. While the mortality rate from ruptured AAA has also fallen since 1991, the overall case fatality rate for ruptured AAA has fallen by only 1·3 per cent (from 80·7 to 79·3 per cent).

Conclusion The decline in mortality rate and emergency procedures may result from a fall in the incidence of ruptured AAA, due to an increasing rate of elective surgery before 1992. The decline in elective procedures from 1992 may be due to a fall in the prevalence of AAA owing to high rates of elective surgery, or to a fall in the incidence of the disease itself.

The rate of elective surgery for abdominal aortic aneurysm (AAA) has increased steadily over the past 30 years[1–5]. This trend has been driven by an improved awareness of the disease, an increased diagnostic rate and the expectation that elective surgery would result in a fall in the incidence of ruptured AAA. However, the incidence of aneurysm rupture between the late 1970s and the early 1990s, and the overall age-standardized mortality rate from AAA, have risen[1–3,5–7]. This rise has generally been attributed to an increase in the incidence of AAA associated with an inadequate diagnostic rate for asymptomatic AAA in an ageing population. There is considerable interest, and controversy, in the role of population screening as a means of reducing the mortality rate from AAA[8–10].

On the basis of anecdotal observations that the number of ruptured AAAs in Western Australia appeared to have fallen over recent years, a review was carried out of the trends in operations for AAA and deaths from AAA in Western Australia between 1985 and 1994.

Patients and methods

Western Australia Health Services Research Linked Database

The Western Australia Linked Database was established in 1995 and currently collates 16 years of inpatient hospital morbidity data, birth and death registrations, midwives' notifications, mental health services data and notifications to the cancer registry. These data constitute around 8 million records and include all hospital admissions and readmissions to public and private hospitals in the State.

Linkage between the six core data sets is based on six Automatch passes with unit medical record number (specific among all metropolitan teaching hospitals, and within all other hospitals), surname, forename, initial, date of birth, sex and address as the principal matching fields. The Western Australia Linked Database has been structured using a chain of links method, which enables the state of linkage between records to be reconstituted as it was found on any previous date. Validation can be performed manually where necessary for any verification required. To protect the confidentiality of patient information a de-identified version of the Linked Database is used for all research purposes. The de-identification process replaces all patient identification data with a unique number.

For this study the morbidity records of all patients readmitted for AAA or dying from rupture before admission in Western Australia were linked for the interval 1985–1994. As the linkage of 1995 mortality data was not complete, additional 1995 data were obtained from the State Health Department and are included in *Fig. 1*.

All patient morbidity records before 1988 were selected using the combined International Classification of Diseases (ninth revision) (ICD9) diagnosis codes (441.30 or 441.40)[11] or International Classification of Procedures in Medicine procedure code (58.53)[12]. Patients admitted from 1988 to 1994 were selected using the combined ICD9-CM diagnosis codes (441.30 or 441.40)[13] or ICD9-CM procedure code (38.44)[14]. Three groups were separated for analysis: patients with 'rupture', those admitted for 'elective' repair and those admitted to hospital with an 'acute aneurysm' (admitted as an emergency without mention of rupture and who underwent repair for AAA). To allow the overall case fatality rate from rupture to be determined within the State, patients with a ruptured aneurysm were further divided into three subgroups: those who died before admission to hospital (based on the primary cause of death as recorded in the State death records), those who were admitted but not

Paper accepted 20 October 1997

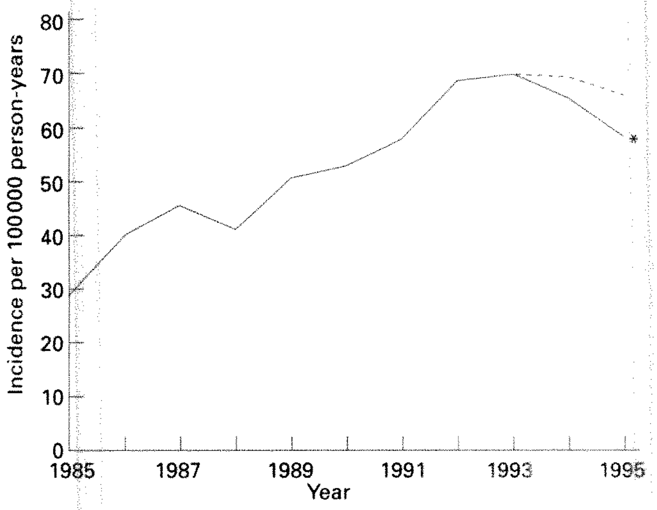

Fig. 1 Age-standardized total (men and women) annual incidence rates of open repair for abdominal aortic aneurysm. Endoluminal stent grafting (ELG) was commenced in 1993. ———, Excluding ELG; -----, including ELG. *1995 incidence estimate obtained from the Health Department of Western Australia

treated surgically and those who were admitted and had aneurysm repair. Selection was restricted to patients aged 55 years and over as cases of AAA under this age were rare (less than 2 per cent of cases) and may be atypical[15]. Data concerning all patients who died from AAA without being admitted to hospital for the study interval 1985–1994 were obtained from the Western Australia Death Register using the ICD9 death code 4413 as coded by the Australian Bureau of Statistics. The de-identified linked research database was current on the 20 November 1996.

All patients admitted with an acute aneurysm underwent operation. In 241 patients (93·8 per cent) this was the primary diagnosis and procedure; the remaining 16 (6·2 per cent) included patients with a variety of other diagnoses (and consequently procedures) including renal cell carcinoma, renal artery stenosis and acute distal occlusive peripheral vascular disease. The only basis for distinguishing these patients in this study was emergency admission. Although some reports include these with elective cases (i.e. a non-rupture group), they were analysed separately in this study as they are different with respect to co-morbidity[16–18].

A specific code for the procedure of endoluminal stent grafting of AAA had not been established. As all these procedures were performed exclusively in one vascular unit (Royal Perth Hospital), accurate data on procedure numbers were available and have been incorporated into *Fig. 1*, but not into subsequent figures.

The index admission for each patient was defined as the hospital admission in which the repair procedure was first carried out. Annual age-standardized and age-specific procedure and mortality rates per 100000 person-years for those aged over 55 years were estimated using the direct method of age standardization[19] and the World Standard Population as the standard set of weights[20]. Men and women were analysed separately. Population estimates were obtained from the Australian Bureau of Statistics (Catalogue 3203.5) and were used as denominators for the calculations. Census population data for 1994 were not available, so estimates were calculated by linear regression using data from the previous 5 years.

In addition to the annual age-standardized and age-specific rates, the crude operative (30-day) mortality rate for patients admitted with aneurysm rupture, acute aneurysm and elective repair was calculated using operation numbers for each category as the denominator (*Table 1*). The total case fatality from rupture was calculated using the total number of ruptured AAAs as the denominator (*Table 2*). As there was considerable annual variation in these rates, the data were grouped into two 5-year intervals to show trends. Differences between the two intervals were evaluated with the χ^2 test with Yates' correction.

Table 1 Crude operative mortality rate at 30 days in men and women admitted for rupture, acute aneurysm and elective repair

	1985–1989	1990–1994	Total	P†
Rupture repair				
Patients	128	155	283	
Deaths	55 (43·0)	47 (30·3)	102 (36·0)	0·04
Acute aneurysm repair				
Patients	157	100	257	
Deaths	16 (10·2)	7 (7·0)	23 (8·9)	0·52
Elective repair				
Patients	250	685	935	
Deaths	12 (4·8)	28 (4·1)	40 (4·3)	0·77
Total repair

Values in parentheses are percentages. AAA, abdominal aortic aneurysm. *1985–1989 *versus* 1990–1994 (χ^2 test)

Results

Between 1985 and 1994, there was a 20 per cent increase (from 1·42 to 1·70 million) in the overall population of Western Australia and a 25 per cent increase (to 307088) in the number of people aged 55 years or more. The increases in the number of men and women aged 55 years or over were similar (26 and 25 per cent respectively). A total of 1475 open repairs for AAA were identified in 1985–1994, of which 85·2 per cent were in men and 14·8 per cent were in women (male to female ratio of 5·8:1). A further 183 open repairs were documented in 1995 (included in *Fig. 1* only). Of all aneurysm repairs performed in Western Australia between 1985 and 1994, 283 (19·2 per cent) were for rupture, 935 (63·4 per cent) were elective and 257 (17·4 per cent) for acute aneurysm repair (*Table 1*). This does not include endoluminal stent grafting, which was introduced at a single institution: two cases in 1993, 11 in 1994 and 24 in 1995.

Procedure rates

A substantial increase (from 27·4 per 100 000 to 70·8 per 100 000 person-years) in the total age-standardized annual incidence rate of open repair for AAA occurred between 1985 and 1993 (*Fig. 1*). After the peak rate of 70·8 per 100 000 person-years in 1993, it fell by around 18 per cent (to 58·2 per 100 000 person-years) in 1995. A small temporary decline of around 8 per cent was observed in 1988, which corresponds to the time at which the coding classification changed from ICD9 to ICD9-CM. The greatest contribution to the changes in the total annual incidence rate was an increase in the number of men undergoing elective surgical repair (*Fig. 2a*).

There was an increase in the age-specific incidence rate of AAA in men of all age groups between 1985 and 1992, after which a decline occurred in all age groups except those aged 65–69 and 75–79 years. The data reflect the general trends seen in *Fig. 1* and show that AAA is uncommon in men aged 55–59 years (mean age-specific rate of 15·7 per 100 000 person-years). The incidence increases steadily to a maximum incidence rate in those aged 75–79 years (mean age-specific rate of 150·6 per 100 000 person-years), and then declines in those aged 80 years or more (mean age-specific rate of 100·2 per 100 000 person-years).

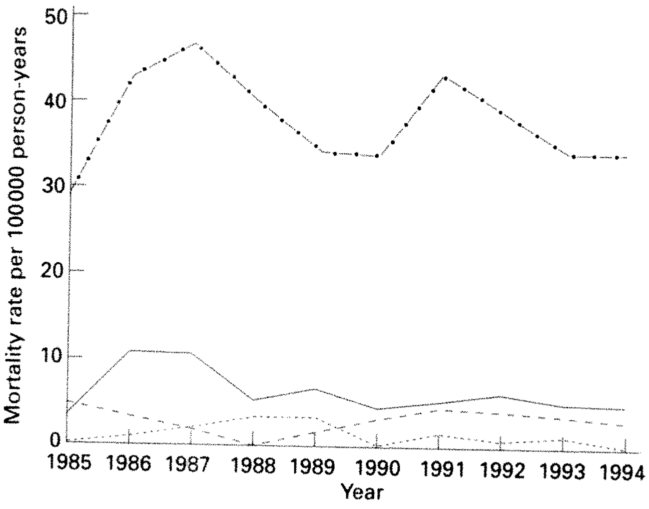

Fig. 3 Age-standardized annual mortality rate from abdominal aortic aneurysm in men with rupture repair (———) (including those who died without surgery (——·——·——)) and those who died within 30 days of admission for acute aneurysm repair (······) and elective repair (— — —)

Mortality rates, operative mortality and case fatality

The age-standardized mortality rate for rupture in men varied considerably during the study (*Fig. 3*), in general reflecting the incidence of rupture (*Fig. 2a*). A similar pattern was seen in women (data not shown). Postoperative deaths after elective and acute aneurysm repair added little to the total mortality rate and there was no obvious trend over time.

The crude operative (30-day) mortality rate after surgery for rupture, acute aneurysm and elective repair is summarized in *Table 1*. Case mortality from rupture including cases not admitted to hospital is summarized in *Table 2*. Although the operative mortality rate for rupture at 30 days fell from 43·0 to 30·3 per cent, the total case fatality fell only slightly from 1985–1989 to 1990–1994.

Discussion

For two decades, studies in Western Australia[1,21], Europe[2,3,5–7] and North America[4,22–25] have reported increasing rates of incidence, surgical treatment and mortality from AAA. The results of this study suggest a fall in these rates since 1992 (*Figs 1* and *2*), a finding that has not been reported previously. In men, there have been falls in the age-standardized rates for non-ruptured and ruptured AAA procedures (*Fig. 2a*), and a fall in mortality from ruptured AAA (*Fig. 3*). A similar trend in elective procedures was seen in women, although the procedure rate for rupture has risen (*Fig. 2b*). These trends were more obvious for men owing to their greater numbers.

The annual rates for ruptured AAA were variable and the recent downward trend may be due merely to temporary variation. It could be speculated that the rate of elective surgery is now high enough to reduce the number of AAAs at risk of rupture, and that this has led to a stabilization or fall in the rates of operation for rupture (*Fig. 2*). The decline in the operation rate has in turn resulted in a fall in age-standardized mortality from rupture (*Fig. 3*).

Although the crude operative mortality rate for emergency aneurysm repair fell by 12·7 per cent at 30 days between 1985–1989 and 1990–1994 (*Table 1*), the 'total case fatality rate' for all ruptures, including patients who died without being admitted to hospital, did not change significantly for the same interval, indicating that the overall salvage rate was unchanged (*Table 2*). These data emphasize the lethal nature of ruptured AAA with over 40 per cent of deaths occurring without hospital admission; these cases are often overlooked in reports using institutional rather than community-based data.

The reason for the possible recent fall in the rate of elective surgery is unclear at present. The authors are unable to identify changes in the management of aneurysms in Western Australia that account for the decline in elective surgery. There is no reason for the diagnostic rate or the referral rate of AAA to have fallen in recent years given the increased use of ultrasonography and improved awareness of AAA. The decline in elective procedures cannot be accounted for by a reduction in the proportion of patients being offered surgery, as the criteria for elective surgery have not changed during the study interval. Nor can the fall be attributed to the introduction of endoluminal stent grafting in Western Australia since 1993 (*Fig. 1*), because its use has generally been restricted to patients at higher risk[26,27]. One possible interpretation is that the previous increase in operation rates (up to 1992) has allowed surgeons to 'clear the backlog' and establish a lower stable rate for elective procedures.

The possibility that trends in the procedure and mortality rate are unrelated to medical intervention but are due to changes in the true incidence rate of AAA needs also to be considered. The incidences of ischaemic heart disease and cerebrovascular disease have fallen in the past few decades[1,28]. These trends have generally been attributed to changes in cardiovascular risk factors[29]. As the dominant risk factors for AAA are the same as those for atherosclerosis[30], the trends in AAA may merely have lagged behind.

There have also been significant changes in the health of the Australian community which may explain why the declining trend for AAA has been observed in Western Australia before Europe or North America. The success of the antismoking movement in Australia[31,32] has contributed to a decline in the mortality rate in men from lung cancer since the mid-1980s[33,34]. This is the first time that this has been reported since the turn of the century[35]. As smoking is an important risk factor for both lung cancer[35] and AAA[36], a similar trend for AAA may be the result as the cohort of lifetime non-smoking men moves into the seventh and eighth decades.

Arteriovenous fistula using transposed basilic vein

P. C. BUTTERWORTH, T. M. DOUGHMAN, T. J. WHEATLEY and M. L. NICHOLSON

University Department of Surgery, Leicester General Hospital, Gwendolen Road, Leicester LE5 4PW, UK
Correspondence to: Mr P. C. Butterworth

Background Patients who need long-term haemodialysis often require multiple operations to maintain their vascular access. The options for secondary or tertiary access procedures may become increasingly limited. Prosthetic conduits are commonly used in difficult cases but are associated with a high incidence of complications.

Methods The brachial artery–transposed basilic vein arteriovenous fistula has been used in preference to a prosthetic graft on 31 occasions.

Results There were no technical failures and 28 of these fistulas matured. No major infective complications occurred.

Conclusion This procedure should be considered before resorting to a prosthetic graft for vascular access.

The provision of long-term vascular access for chronic haemodialysis remains a surgical challenge. The radiocephalic fistula of Brescia and colleagues[1], fashioned in the non-dominant arm, remains the undisputed first choice access procedure. However, a number of patients lack suitable vein in the forearm and thus alternatives are required. In addition, the extended life expectancy which has accompanied improvements in haemodialysis techniques can necessitate secondary and occasionally tertiary access procedures. If the cephalic vein is unsuitable in the upper arm, the choice of conduit is between prosthetic graft or transposed basilic vein. The deep subfascial position of the basilic vein protects it from cannulation or repeated venepuncture and it is generally of large calibre. Brachiobasilic arteriovenous fistula using transposed basilic vein was first described in 1976[2] but its place in the provision of long-term vascular access remains uncertain. Originally described as a tertiary procedure it has also been advocated as the second choice after Brescia–Cimino fistula[3]. In this unit, brachiobasilic fistulas have been fashioned in preference to use of a prosthetic graft in the small number of patients in whom the cephalic vein was not available in either arm. This report outlines the authors' experience with this procedure.

Patients and methods

Brachiobasilic fistulas were fashioned using a technique similar to that described by Dagher *et al.*[2]. At each operation a single preoperative dose of co-amoxiclav 1·2 g was given intravenously. A transverse incision was made in the antecubital fossa and the deep fascia opened medially to expose the basilic vein. The incision was then extended up the medial side of the arm ('hockey stick' incision) and the whole length of the basilic vein was mobilized from beneath the fascia, taking care to preserve the medial cutaneous nerve of the forearm. Communicating tributaries were divided between 3/0 polyglactin ligatures and the vein was divided distally in the antecubital fossa. It was then transposed to a subcutaneous tunnel on the anterior surface of the arm and anastomosed end to side to the brachial artery in the antecubital fossa using 7/0 polypropylene (*Fig. 1*). A suction drain was sited beneath the deep fascia in the original site of the basilic vein, and an epidural catheter was placed in the axillary sheath to facilitate postoperative regional analgesia[4]. The wound was then closed in two layers. The drain was removed when there was less than 30 ml drainage fluid in the previous 24 h. The fistula was allowed at least 6 weeks to develop before venepuncture for dialysis.

Data concerning development of the fistula and use for dialysis were collected by retrospective review of the case notes and by prospective enquiry of individual patients and dialysis units.

Results

Thirty-one brachiobasilic fistulas were fashioned in 30 patients, ten men and 20 women of median age 60 (range 32–77) years. The left arm was used in 18 patients and the right arm in 13. In 13 patients this was the first vascular access procedure; suitable forearm or upper arm cephalic vein was absent. Seventeen patients had previously had arteriovenous fistulas: the median number of previous access procedures in this group was 2 (range 1–9).

There were no technical complications: all 31 fistulas were patent at 6 weeks. There was no perioperative death.

② = Brachial artery
③ = Arteriovenous anastomosis-end to side
④ = Basilic vein transposed to subcutaneous position

Fig. 1 Use of the basilic vein for arteriovenous fistula

Paper accepted 4 September 1997

There were four postoperative complications involving the wound: two postoperative haematomas, one wound infection which responded to oral antibiotics and a lymph leak from the antecubital fossa which settled spontaneously. No fistula subsequently became infected.

Of 31 procedures, 28 fistulas matured sufficiently to allow needling for dialysis. One patient died from cardiovascular causes before maturation. One fistula failed to develop as a consequence of a stenosis in the basilic vein and a third fistula was found to have thrombosed after the initial puncture. However, only 23 fistulas have been used for dialysis; two patients recovered renal function and one patient elected to return to peritoneal dialysis. Two fistulas were ligated before they were used because of steal phenomena which failed to settle. High-output heart failure, previously reported as a complication of arteriovenous fistula involving the brachial artery, was not seen.

Of 23 fistulas which have been used regularly for dialysis, 18 are still being used after a median follow up of 8 (range 2–18) months. Two patients have had a renal transplant and the fistulas are no longer in use but remain patent. In addition, one fistula remains patent but is no longer in use because of a bleeding diathesis. One fistula has failed because of multiple stenoses consequent upon repeated needling and a second has been ligated because of arm swelling secondary to a subclavian vein occlusion which occurred 14 months after the fistula was fashioned.

Discussion

Patients who require long-term haemodialysis need long-term vascular access. Multiple operations may be required to maintain access as time passes. The radiocephalic forearm fistula of Brescia and Cimino is well established as the operation of first choice and has a good long-term patency rate, once established. Unfortunately, adequate vein in the forearm is often not available[5]. In this situation a fistula fashioned by end-to-side anastomosis of the upper arm cephalic vein to the brachial artery in the antecubital fossa has been the procedure of second choice. If all the superficial veins are unavailable, formation of an arteriovenous fistula necessitates the use of either transposed autologous vein or a prosthetic graft. The patency rates of polytetrafluoroethylene grafts in this situation are 65–70 per cent at 1 year[3,6] and 50–65 per cent at 3 years[5,7]. However, these encouraging patency rates are only achieved at the expense of a considerable number of complications. A significant rate of spontaneous thrombosis is seen in prosthetic grafts such that an average of one thrombectomy operation per graft per year is required to maintain patency[8]. Furthermore, graft infection is dauntingly common, with rates of up to 15 per cent[9], and usually necessitates removal of the graft. This can be serious if the options for revision or establishment of temporary access are limited. Autologous vein has less tendency to spontaneous thrombosis and infection is usually treatable without loss of the fistula. Vein transposition does not preclude subsequent use of a prosthetic conduit at the same site[10] whereas it is unlikely that the converse would be successful. The brachiobasilic fistula gives patency rates approaching 60 per cent at 3 years in the hands of the originators of the technique[11,12] and these results have been matched in a large European series[13]. Published experience with this procedure in the UK is limited[14]. The present series is not sufficiently large to allow meaningful life-table analysis but the results are sufficiently encouraging to suggest that the brachial artery–transposed basilic vein arteriovenous fistula can form a valuable part of the vascular access surgeon's armamentarium.

Multimodality treatment in the control of deep musculoaponeurotic fibromatosis

A. I. SKENE, L. BARR, R. P. A'HERN, C. FISHER and J. MEIRION THOMAS

Sarcoma and Melanoma Unit, Royal Marsden Hospital, Fulham Road, London SW3 6JJ, UK
Correspondence to: Mr A. I. Skene, Yew Tree Cottage, Derritt Lane, Bransgore, Dorset BH23 8AT, UK

Background Deep musculoaponeurotic fibromatoses are rare soft tissue neoplasms with a propensity for local recurrence.

Methods A retrospective analysis was carried out of the factors contributing to local disease control in 75 patients treated between 1963 and 1993.

Results Multivariate analysis identified the type of surgical excision ($P < 0{\cdot}001$) and involvement of pathological resection margins ($P < 0{\cdot}02$) as significant factors contributing to local recurrence. After a median follow up of 47 months (range 24 months to 29 years) 31 (49 per cent) of the 63 patients who had an 'adequate' surgical resection developed local recurrence. The median time before development of local recurrence was 83·4 (range 8–129) months in patients with clear pathological resection margins. This was significantly shortened to 13·1 (range 2–35) months in those with positive margins ($P < 0{\cdot}001$).

Conclusion Adequate surgical extirpation is the most important determinant in local disease control. Treatment of local recurrence ranged from observation during periods of disease stabilization to multimodality treatment for aggressive disease.

Musculoaponeurotic fibromatoses or desmoid tumours are rare soft tissue neoplasms constituting 0·03 per cent of all tumours with an incidence of 3·7 new cases per 10^6 of the population[1].

The growth pattern of these lesions mimics that of low-grade malignant tumours with a propensity for local tissue invasion. They present diagnostic as well as treatment difficulties. Although these tumours are 'benign' by virtue of being non-metastasizing, they are potentially hazardous because of their ability to grow to a large size, to interfere with function, to ulcerate and to involve vital structures. This study evaluates the factors contributing to local tumour control.

Patients and methods

A retrospective study was carried out on patients presenting with deep fibromatoses between 1963 and 1993. Ninety-five patients were assessed initially. Patients with superficial fibromatosis and those with Gardeners syndrome were excluded from this analysis.

Definitive histology was obtained in all cases, either by pathological review of outside material or, when inadequate, by further biopsy. Fibromatosis is an infiltrating proliferation of uniform bland fibroblasts and myofibroblasts (which also shows some of the features of smooth muscle cells) evenly dispersed within a collagenous stroma containing characteristic blood vessels and frequent mast cells[2]. The histological sections were all reviewed by a single pathologist.

Five patients with less than 2 years' follow-up and three with a revised diagnosis were excluded from subsequent analysis. Twelve further patients from abroad were lost to follow-up shortly after diagnosis leaving a total of 75 evaluable patients with a substantiated diagnosis of deep musculoaponeurotic fibromatosis.

Patient treatment was based on the principles of management developed from an extensive experience treating adult soft tissue sarcomas at this centre. The treatment plan was where possible on anatomical grounds to achieve wide surgical resection. In patients where only a marginal resection was possible consideration was given to adjuvant radiotherapy.

Twenty-seven patients presented with a previously untreated mass, 37 patients were referred for management of a local recurrence and an additional 11 patients were referred with inoperable disease. Preoperative assessment in the later part of the series involved computed tomography (CT). Patients were followed up at 3-month intervals for the first 2 years, 6 monthly for the next 2 years and yearly thereafter.

The initial treatment was surgical in 64 (85 per cent) of the patients. The principal aim of surgery was to obtain wide local clearance of tumour in order to achieve local control, whilst striving to preserve function. The surgical clearance achieved by initial surgery was recorded according to the Enneking classification[3], and was radical in seven patients, wide in 23 patients, marginal in 32 and intracapsular in 13 patients. To fulfil the surgical aim 32 of the 37 patients initially treated elsewhere had further surgery when referred, 28 having previously had a marginal excision and four with tumours for which only open diagnostic biopsy had been performed.

The majority of patients ($n = 52$, 69 per cent) did not receive radiotherapy. Thirteen of 37 patients had radiotherapy after surgical resection of locally recurrent disease. Five of 11 patients who presented with inoperable disease had primary radiotherapy and five patients with no evaluable disease received adjuvant radiotherapy after surgical resection.

Chemotherapy was only given to four patients (5 per cent), one with inoperable disease of the head and neck and to three patients for control of resistant local recurrence that had progressed despite other treatment.

Patients with inoperable or recurrent disease were treated initially by observation and/or hormonal manipulation with tamoxifen or its chlorinated analogue toremifen. Patients with progressive symptomatic disease had a combination of palliative chemotherapy, radiotherapy and debulking surgery.

The age and sex distribution of the patients is shown in *Fig. 1*. Disease-free survival was measured from the time of definitive diagnosis for the 63 patients having surgery with curative intent using the Kaplan–Meier product limit method and compared by the log rank test[4] (*Figs 2* and *3*).

Abdominal and chest wall	19 (25)
Intra-abdominal	6 (8)
Pelvis	9 (12)
Lower limb	15 (20)
Total	75 (100)

Results

The median age of the patients was 30 (interquartile range (i.q.r.) 21–41) years, there were 50 female and 25 male patients. The commonest presenting feature was a slow growing mass ($n = 63$; 84 per cent) with a median diameter of 6·5 (i.q.r. 4–10) cm. Only one patient had multifocal disease at presentation. The median follow-up for survivors was 47 months (range 24 months to 29 years). *Table 1* shows the anatomical distribution of these tumours.

Local recurrence developed in 14 of the 30 patients treated by wide or radical surgical resection. However, 30 of the 33 patients with initial marginal or intracapsular resections had residual disease or early recurrence at the time of referral. Seventeen of these 33 patients were subsequently salvaged at this centre by additional surgical resection alone. In total 31 (49 per cent) of the 63 operable patients developed local recurrence after definitive resection and initial surgical control of disease.

Multiple recurrences developed in 24 (32 per cent) of the 75 patients observed over the follow-up period. Eight patients had two recurrences, ten had three and six had four or more. Two of these patients had a total of nine recurrences and eventually died from progressive disease within the abdomen and neck regions despite multimodality treatment.

The median time to development of a clinical recurrence requiring a change in treatment in patients with clear pathological margins was 83·4 (range 8–129) months. In patients who had involved pathological margins the median time to recurrence was significantly reduced ($P < 0{\cdot}001$) to 13·1 months although there was a wide range from 2 to 35 months. Of the 26 patients who subsequently were treated by further surgery achieving clear pathological margins 16 developed a second recurrence after a mean of 21·2 months, not significantly shorter than that achieved by adequate primary surgery.

Univariate and multivariate analysis of the clinical and pathological treatment variables on the rate of local recurrence was carried out as shown in *Table 2*. In the univariate analysis, of the pathological features analysed, the type of surgical excision and the adequacy of surgical margins significantly influenced the rate of local recurrence. A marginal surgical resection, clinically involved surgical margins and involved pathological resection margins were each associated with a significantly increased risk of local recurrence.

In a multivariate analysis all co-variates listed in *Table 2* were entered into a Cox proportional hazards model. Of the co-variates analysed the type of surgical resection and the involvement of pathological margins were both found to be independent risk factors. Wide or radical surgical resections ($P < 0{\cdot}001$) and clear pathological resection

Table 2 Univariate and multivariate analysis of factors contributing to local recurrence

	Hazard ratio	P
Significant factors on univariate analysis		
Operative resection		
Radical and wide	1·00	0·0001
Marginal and simple	4·74 (2·41–9·29)	
Surgical macroscopic clearance		
Achieved	1·00	0·001
Not achieved	3·16 (1·68–5·94)	
Pathological resection margins		
Clear	1·00	0·0001
Involved	4·69 (1·96–11·10)	
Significant factors on multivariate analysis		
Operative resection		
Radical and wide	1·00	0·001
Marginal and simple	3·28 (1·58–6·85)	
Pathological resection margins		
Clear	1·00	0·02
Involved	2·82 (1·10–7·14)	

Values in parentheses are 95 per cent confidence intervals. Co-variates in the multivariate analysis were age (less than 20, 20–30, more than 30 years), site of tumour, size of tumour (less than 5 cm, more than 5 cm), primary treatment, surgical clearance, pathological involvement of resection margins, type of surgical resection, number of recurrences, radiotherapy

margins ($P < 0·02$) were associated with a decreased risk of local recurrence.

Of the 63 patients who had surgery as the primary treatment modality 50 are disease free, 11 are alive with recurrence and two have died from disease. Of the 11 with recurrence four have progressive disease despite multimodality treatment, and seven have disease stabilization and are currently being treated by hormone manipulation or observation only.

A total of 14 patients had a period of hormone manipulation or observation only for recurrent or inoperable disease. Disease stabilization lasting over 1 year was found in four patients and over 6 months in a further five patients. Complete resolution was observed in one patient. Progressive symptomatic disease requiring a change of treatment occurred in the other four patients observed initially.

Discussion

The local invasion of fibromatosis[5,6] and the frequent recurrences have led some institutions to consider them as malignant soft tissue neoplasms[7–10]. Despite the benign pathology in terms of management the authors consider them equivalent to low-grade soft tissue sarcomas. Although fibromatoses frequently recur locally they have no metastatic potential. It is important for them to be distinguished from the histologically similar low-grade fibromyxoid sarcoma[11].

The natural history of untreated fibromatosis is one of slow progressive invasion of contiguous structures. Although the majority of patients who had an inadequate resection in this series went on to develop a local recurrence a long latent period of disease stabilization in some patients with evaluable disease was observed. This has led to an initial observation policy for local recurrence in areas where further adequate re-excision would result in functional impairment. Only one patient with a complete spontaneous resolution of tumour was observed. This rare phenomenon cannot be relied upon.

This series records several interesting features of the disease. These include complete spontaneous resolution, an occasional dramatic response to hormone manipulation, long quiescent periods after periods of rapid growth and the observation that not all tumours excised with positive resection margins progressed into a clinical recurrence.

The preponderance of deep fibromatosis in women of child-bearing age together with the rare spontaneous tumour regression seen during menarche and at the menopause raises the possibility of manipulative endocrine therapies. Although the precise relationship between these fibromatoses, the endogenous hormonal environment and exogenously administered endocrine therapies is far from clear, there is an established therapeutic relationship. Endocrine manipulations have resulted in some dramatic responses but there have been frequent failures[12].

Some authors have commented on the strong association with trauma[13]. Antecedent trauma or surgery was recorded in only one patient (1·3 per cent) in this series. It should be noted that minor trauma is common and, although not causative, may bring a patient's attention to a previously unnoticed mass.

Adequate surgical extirpation is clearly the most important determinant of local disease control as suggested by previous studies[7,14–16]. The more conservative approach advocated by some institutions[1,16–18] cannot be recommended. There appeared to be a local disease control advantage only if there was macroscopic clearance of tumour. The present findings suggest that 'salvage' wide excision following an initial incomplete excision conferred a similar advantage to initial wide excision, with no detriment to ultimate disease control.

The adjuvant effect of radiotherapy is less easy to verify. The initial results of Musgrove and McDonald[19] were interpreted as showing no role for radiotherapy. More recent series using megavoltage equipment have shown a more consistent response[20–26]. Relapse was associated with lower total dose (less than 50 Gy), small field size and orthovoltage techniques. Adjuvant radiotherapy was not given routinely in this series, to reduce the potential long-term sequelae of such treatment. Radiotherapy was confined to patients with inadequate tumour clearance where a wider clearance was not feasible on anatomical or functional grounds, or where recurrence had occurred with a short disease-free interval.

Unfortunately there are groups of patients in whom neither wide surgical resection nor radical radiotherapy may be feasible because the anatomical location, extent of disease and encroachment of vital organs render these treatment modalities inappropriate.

The characteristic infiltrative nature of desmoid tumours together with their frequent deep location renders their precise clinical anatomical localization difficult. CT and nuclear magnetic resonance imaging both contribute to the assessment of tumour extension and should be considered in all treatment planning which relies on identification of tumour margins. The deep fibromatoses have characteristic appearances on CT demonstrating homogeneity both before and after administration of intravenous contrast.

In conclusion, wide excisional surgery whenever possible should be considered the treatment of choice.

The overall additional benefit of radiotherapy remains controversial and to avoid late sequelae in a relatively young group of patients the authors do not use this modality routinely. In some patients recurrent disease can plateau after a period of rapid growth and can remain stable with minimal symptoms for long periods of time. This observation has modified the criteria for treatment of recurrent disease and an initial period of observation may be permissible.

Anovestibular fistula to Bartholin's gland

N. P. J. CRIPPS and J. M. A. NORTHOVER

St Mark's Hospital, Northwick Park, Watford Road, Harrow HA1 3UJ, UK
Correspondence to: Mr J. M. A. Northover

Background Acquired fistulation from the anal canal to Bartholin's gland has not been reported before. This fistula has been identified in 11 women treated between 1991 and 1995.

Methods All discharge diagnoses during this period were searched. The clinical records of patients managed for this diagnosis were reviewed.

Results Eleven women aged 24–49 years were identified. Seven of 11 fistulas arose in association with inflammatory bowel disease (five Crohn's disease, two ulcerative colitis). Patients typically presented with the vulval passage of flatus and faeces or acute sepsis of Bartholin's gland. Time to diagnosis of the fistula ranged from 1 to 15 (median 8) months after the onset of symptoms. Anatomically, all fistulas were high trans-sphincteric or suprasphincteric. All eight fistulas for which repair was attempted (five in the presence of inflammatory bowel disease) remain healed at short-term follow-up. Proctocolectomy was undertaken in two patients with severe Crohn's colitis.

Conclusion Ano–Bartholin's fistulas, although rare in general surgical practice, present with troublesome symptoms and may be repaired successfully. Gynaecologists and surgeons should be aware of this clinical entity to avoid unnecessary delays in treatment.

Either through uncertainty or embarrassment, women may delay reporting the vulval passage of flatus or faeces. Clinical diagnosis of proctovaginal fistula of any configuration rests on the positive identification of a fistulous tract. Most such fistulas are quite easily confirmed by identification of the vaginal opening in the vicinity of the posterior fourchette. However, if the vaginal opening cannot readily be detected, the correct diagnosis may be further delayed. Thus, one reason for diagnostic difficulty is unusual fistula anatomy. To the authors' knowledge, no previous description of spontaneously acquired ano–Bartholin's fistula exists in the literature although it is suspected that anovestibular fistula to Bartholin's gland is more common than its limited bibliography suggests.

Patients and methods

The hospital records of 11 women aged 24–49 (median 34) years who had the diagnosis of ano–Bartholin's gland fistula made or referred to in the course of their management between 1991 and 1995 were reviewed. A further patient seen several years earlier was included because clinical photography of the case is particularly illustrative (*Fig. 1*).

Results

Seven fistulas were found in women with inflammatory bowel disease (IBD), two of whom had ulcerative colitis and five had Crohn's disease; two of the latter had no previous anal lesion. Four had no evidence of IBD; the aetiology of these fistulas was assumed to be idiopathic anal sepsis. In all cases, standard clinical and histopathological criteria for the differential diagnosis of IBD were used by staff at St Mark's Hospital. Symptom duration was 1–15 (median 8) months before diagnosis which was generally made under anaesthesia. All fistulas were classified anatomically as high trans-sphincteric or

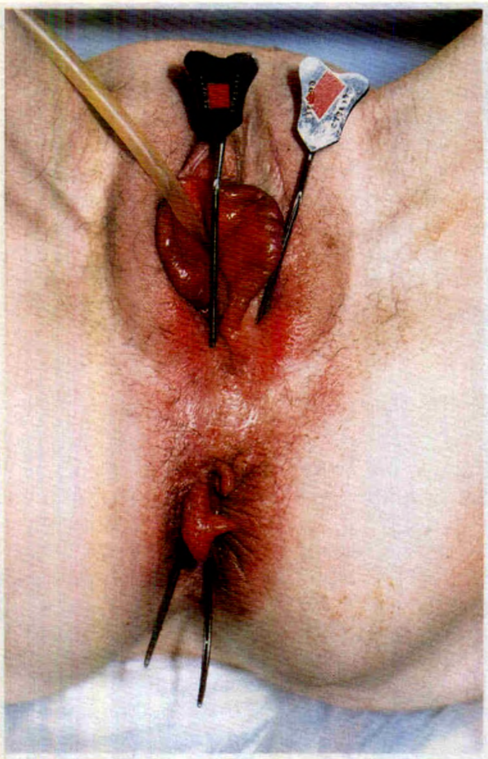

Fig. 1 Two fistula probes pass from the vulval openings of Bartholin's glands to a single internal opening in the anal canal in a patient with Crohn's disease. Of particular note is the absence of inflammation or granulation tissue in the region of the glandular orifice. This patient was managed by proctocolectomy because of her generally poor state of health from concomitant pulmonary disease

Paper accepted 12 August 1997

Table 1 Clinical details of patients with anal fistula to Bartholin's gland from 1991 to 1995

Age (years)	Inflammatory bowel disease at diagnosis	Perineal symptoms	Symptom duration (months)	Diagnostic tool	Fistula anatomy	Treatment	Fistula healed
32	Crohn's disease	Severe perineal sepsis	2	EUA	Suprasphincteric	Ileostomy and fistula laid open; subsequent repair	Yes
25	Ulcerative colitis	Acute vulval abscess	1	EUA	Suprasphincteric	Advancement flap	Yes
34	Ulcerative colitis	Faeculent p.v. discharge	15	Anal ultrasonography	Suprasphincteric	Seton then advancement flap	Yes
24	None	Bartholin's 'cyst'	8	EUA	High trans-sphincteric	Advancement flap	Yes
40	None	Bartholin's abscess	11	EUA	High trans-sphincteric	Excision and sphincter repair	Yes
28	Crohn's disease (not anal)	Bartholin's cyst marsupialized, then p.v. discharge	12	EUA	High trans-sphincteric	Excision and sphincter repair	Yes
37	None	Faeculent p.v. discharge; three previous Bartholin's operations	12	EUA	Suprasphincteric	Advancement flap	Yes
49	Crohn's disease (colon)	Bartholin's cyst, then abscess and p.v. discharge	6	EUA	Suprasphincteric	Proctocolectomy	—
34	None	Bartholin's cyst drained, then faeculent discharge	6	EUA	High trans-sphincteric	'Permanent' loose seton	No
39	Crohn's disease (not anal)	Faeculent p.v. discharge	12	EUA	Suprasphincteric	Excision and sphincter repair	Yes, two operations
47	Crohn's disease (colon)	Severe perianal sepsis	1	EUA	Suprasphincteric	Proctocolectomy	—

EUA, examination under anaesthesia; p.v., per vaginum

suprasphincteric. Some fistulas found in association with Crohn's disease were complex or bilateral (*Fig. 1*).

Closure of the fistula was achieved in the majority of cases. One woman (without IBD) had complete symptom control after placement of a loose seton and has deferred further treatment to date. Other fistulas were closed either by advancement flap repair or by excision of the track and anterior sphincter repair. All eight fistulas in which repair was attempted (five in the presence of IBD) remain healed at short follow-up. Proctocolectomy was undertaken in two women with severe perianal Crohn's disease.

Discussion

Congenital anovestibular and anovulvar fistulas with a normal anus are very rare in clinical practice[1,2] and iatrogenic, acquired fistulas have been reported only twice in the literature[3,4]; diagnosis of the condition may be delayed for this reason alone. Further evaluation of the records in this institution identified approximately 60 women who received treatment for more usually configured anovaginal or rectovaginal fistulas (the distinction between these is difficult because of an overlap in terminology between the two). Ano–Bartholin's fistula, therefore, seems to be a relatively uncommon occurrence compared with the 'standard' fistula, although relative frequencies of these conditions are distorted by referral practices to the hospital, and the fact that many proctovaginal fistulas were identified after restorative proctocolectomy.

Bartholin's (greater vestibular) glands are derived from diverticula arising from the epithelial lining of the urogenital sinus once it has separated from the hindgut. Thus, a developmental anomaly which would readily account for a fistula arising between Bartholin's glands and the anal canal is unlikely[5]. It is more probable that the fistula described here is initiated by idiopathic anal sepsis tracking anteriorly rather than infection in Bartholin's gland spreading back to the anal canal. The particular importance of this clinical entity is that the 'external' opening of the fistula is not readily identifiable in its common site in the posterior fourchette; very often, unless it is associated with Bartholin's gland sepsis, its vulval orifice is normal in appearance or only slightly oedematous. The fistula can be identified only by palpation of subcutaneous induration leading from the anus to the region of the gland in the labium majora.

Two similar reports refer to rectovaginal fistulas secondary to excision of Bartholin's gland, suggesting that the rectal wall was breached at operation[3,4]. In one of these patients the fistula was not related to the anal sphincter and was probably of different aetiology. In the present similar cases, Bartholinectomy had not been undertaken; damage to the anal canal would have been improbable during lesser surgery.

Many patients with Crohn's disease expect perineal symptoms and may not declare them, perhaps for fear of a defunctioning stoma; thus, fistulas occurring in association with IBD may be tolerated for longer than the idiopathic variety. Despite this, considerable periods elapsed between symptom onset and diagnosis, particularly in those with idiopathic fistulas. Although the most frequent source of perineal fistula in Crohn's disease is the anus, another possibility is that extragastrointestinal Crohn's disease may arise primarily in the vulva. This situation has been reported previously when vulval lesions containing Crohn's granulomata unconnected to the gastrointestinal tract were found in three patients[6].

It is concluded that when suggestive symptoms are reported without an evident anovaginal fistula, women should be investigated by examination under anaesthesia to exclude an ano–Bartholin's gland fistula. Furthermore, during surgery for acute Bartholin's gland sepsis, examination of the anus should be undertaken to exclude primary anal pathology. Surgical treatment of such fistulas offers an excellent chance of healing.

Acknowledgements

The authors are grateful to Mr P. R. Hawley, Mr J. P. S. Thomson, Mr R. J. Nicholls and Mr R. K. S. Phillips for allowing their cases to be reported and to Dr K. Wilkinson of the Research Records department for help in identifying the patients.

Background A prospective comparison of laparoscopic or laparoscopically assisted colorectal resection *versus* open resection has been undertaken to evaluate early benefits and cost implications.

Methods Consecutive patients with colorectal cancer underwent either elective laparoscopic ($n = 25$) or open ($n = 29$) resection.

Results Mean hospital stay was significantly shorter in the laparoscopic group: 10·7 *versus* 17·8 days. Mean morphine requirements were less in patients who had laparoscopic resection and their recovery, as measured by the dynamometer hand grip and the SF-36 symptom score, was more rapid. Adequate tumour clearance was achieved in the laparoscopic group. In both groups, the number of lymph nodes harvested was similar. Port-site or wound recurrence has not been observed at a median follow-up of 28 months.

Conclusion When laparoscopic colorectal resection is possible, there are significant early benefits for patients.

The application of laparoscopic techniques to the resection of colorectal cancer has not gained universal acceptance for three main reasons: the learning curve is longer than that for laparoscopic cholecystectomy; there have been reports of cancer implantation in laparoscopic port sites[1–5]; the presence of an anastomosis or stoma prevents rapid discharge from hospital. Provided minimal access techniques do not compromise cancer cure it is appropriate to question whether laparoscopic colorectal resection improves recovery compared with conventional surgery. Patients undergoing resection for colorectal cancer were studied prospectively and results following laparoscopic resection were compared with those following open operation.

Patients and methods

From February 1994 for 24 months, consecutive patients undergoing elective resection for colorectal cancer had either laparoscopic or laparoscopically assisted resection or open resection. Indications for open resection were: patient preference, gross obesity, widely separate synchronous tumours, tumour fixation and/or a palpable mass (7 cm or more). Patients who presented as an emergency or who required urgent surgery, within 1–2 days of admission, were excluded.

All operations were performed by one surgical team under general anaesthesia and standard antibiotic prophylaxis. The techniques of laparoscopic and laparoscopically assisted resection have been described elsewhere[6]. Mobilization of the bowel and ligation of the vascular pedicle was carried out intracorporeally; individual clips or ligatures were used for the vessels, not stapling devices. Bowel anastomosis was performed either by hand, through a small incision, or stapled as in anterior resection. All wounds, including laparoscopic port sites, were lavaged with a 1 in 10 solution of povidone–iodine and the rectum was washed with the same solution before construction of the anastomosis. Patients with mid or low rectal cancer underwent total mesorectal excision[7,8].

Pain relief after operation was by intravenous morphine in the form of patient-controlled analgesia. Pain scores were measured using a linear analogue scale at 6 h, and 1, 2 and 3 days after operation. Morphine requirements were calculated for the same intervals. The dynamometer, which measures grip strength, was used to assess protein loss[9]. Measurement of weight, mid upper arm circumference, serum albumin concentration and dynamometer grip strength were made before operation, and at 1 and 6 weeks after surgery. The SF-36, a standard health evaluation questionnaire[10], was completed by the patient before operation, and at 2 and 4 months after operation. Data were also collected to analyse duration of operation and hospital stay, blood loss and transfusion requirement, readmission within 30 days of surgery, 30-day mortality rate, number of lymph nodes resected and the cost of each intervention (*Table 1*). Histological staging was based on Dukes classification[11].

Statistical analysis

Differences between groups were analysed using the t test and χ^2 test as appropriate. Allowance for potential confounding factors was made using analysis of covariance and linear regression. Where necessary logarithmic transformations were performed to bring skewed distributions nearer to normal and to ensure homoscedasticity.

Results

Laparoscopic resection was attempted in 25 patients, but in three conversion to open surgery was necessary. For purposes of analysis these three patients were included in the laparoscopic resection group as the intention had been to treat them laparoscopically. All other patients in the laparoscopic group underwent laparoscopically assisted resection, except two in whom abdominoperineal excision of the rectum (APR) was performed wholly laparoscopically. *Table 2* lists the operative procedures undertaken and *Table 3* the results following surgery.

Table 1 Cost of operation (£)

Cost of operation is calculated as the sum of:
Stay in Yeovil Hospital (days) × 165
Time in theatre (h) × 164
Stay in convalescent hospital (days) × 80
Cost of disposable equipment
Blood transfused (units) × 32
Cost of extra hospital stay if readmitted within 30 days
Cost of reoperation if necessary

*Values are mean(s.d.). ASA, American Society of Anesthesiologists. †$P = 0{\cdot}001$, ‡$P < 0{\cdot}05$, §$P = 0{\cdot}06$, ¶$P = 0{\cdot}09$ *versus* open resection (*t* test)

The median age, tumour stage and American Society of Anesthesiologists (ASA) status were similar for patients in both groups (*Table 3*). Patients undergoing open anterior resection had tumours situated closer to the anal verge than those undergoing laparoscopic anterior resection (median 7 *versus* 13 cm). The anastomoses were situated at a similar median distance from the anal verge (3 cm). Patients who had open resection had a higher rate of stoma formation: five of seven *versus* two of six. The preponderance of APRs in the laparoscopic group occurred because an attempt was made to treat all low rectal tumours laparoscopically. The median distance of tumours from the anal verge in patients who had APR was 2 cm; all but one were within 3 cm. In two patients open APR was performed, one because of patient preference and the other for tumour fixation.

There were no intraoperative complications in patients undergoing laparoscopic resection such as haemorrhage, bowel perforation or ureteric injury. Three deaths occurred. One patient who underwent open anterior resection and left nephrectomy for renal adenocarcinoma died in renal failure at 14 days. Post-mortem examination revealed a second renal cell tumour. A second patient underwent open sigmoid colectomy, required a Hartmann procedure after 6 days for anastomotic leakage and died at 27 days from adult respiratory distress syndrome. One patient underwent a laparoscopically assisted anterior resection without a stoma for a proximal rectal tumour, had an anastomotic leak at 7 days and died at 10 days from fulminating sepsis despite conversion to a Hartmann procedure.

Hospital stay was significantly shorter in patients treated by laparoscopic resection (*Table 3*). Although laparoscopic resection increased operating times and the cost of disposable equipment, the total cost was less than for open resection (*P* not significant). Morphine requirements following laparoscopic resection were significantly lower than those after open resection (*Fig. 1*), but differences in pain scores did not reach significance. Differences in albumin concentration, weight, mid upper arm circumference and dynamometer grip strength between the two groups were not significantly different compared with preoperative values. Despite this, the

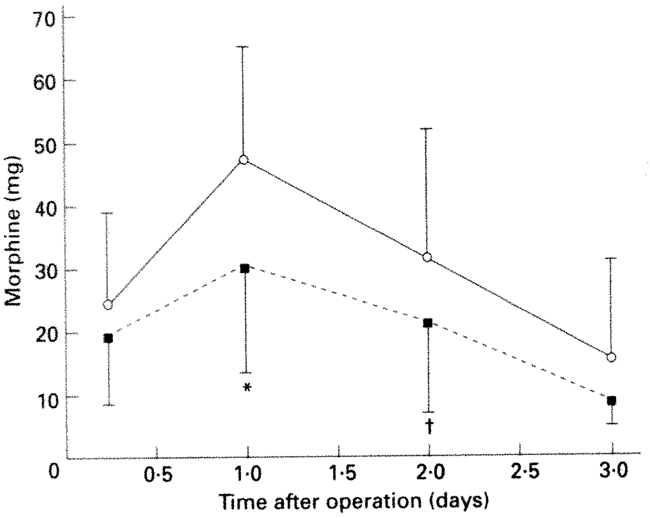

Fig. 1 Mean(s.d.) postoperative morphine requirement following laparoscopic (■) and open (○) colorectal resection. *$P = 0{\cdot}002$, †$P = 0{\cdot}06$ *versus* open resection (*t* test)

reduction in grip strength observed following open operation persisted for 6 weeks, whereas there was no reduction in this parameter at 6 weeks after laparoscopic resection (*Table 3*).

Analysis of results using the SF-36 questionnaire revealed that in six of the eight areas of questioning there was less impairment in health following laparoscopic resection (when compared with preoperative values) than open operation. This trend persisted at both 2 and 4 months but the difference was significant only in the 'general health' questions and then only at 2 months after operation. In two of the eight dimensions of the SF-36 the patients who had open resection had less impairment than those who had a laparoscopic procedure.

No port-site metastasis or unexpected locoregional recurrence has been detected after a laparoscopic procedure.

To allow for possible confounding factors, differences between groups were analysed while controlling for ASA grade, Dukes stage and age. Although some of these factors were significantly associated with the measured outcomes (e.g. age significantly affected length of stay), their inclusion in regression models did not alter the associations between operation type and outcomes described above for the simple analyses.

Discussion

This study has demonstrated a significantly shorter hospital stay in the patients selected for laparoscopic resection of colorectal cancer, by comparison with open resection. Dynamometer measurements and assessments using the SF-36 questionnaire supported the impression that recovery following laparoscopic resection was more rapid; some of the trends were even present 4 months after operation. Although sample sizes were small and the technique relatively new, these results justify further assessment. The selection criteria for each operative technique may have biased results and this needs to be addressed by a randomized controlled trial.

Short-term benefits of laparoscopic resection are irrelevant if they reduce the rate of tumour clearance, unless laparoscopic techniques compensate in some other way, for example by decreasing operative mortality. Most patients with port-site recurrence had advanced disease at the initial procedure or at the time the recurrence was diagnosed[12,13]. There have, however, been reports of local recurrence in patients with histologically early tumours[3,14]. The authors followed a policy of avoiding contact between laparoscopic instruments and the tumour, as well as meticulous lavage of all wounds with a cytocidal agent. The present results are similar to those of three of the largest reported studies, both with respect to local recurrence[15] and to lymph node numbers in the resection specimen[16,17]. This does not provide grounds for complacency, but neither should minimal access techniques be rejected unless there is sound proof of an oncological disadvantage.

These results of laparoscopic or laparoscopically assisted resection suggest that early benefits exist in patients selected for this type of surgery compared with conventional surgery. This trend was present for at least 4 months after operation, longer than described by others.

Acknowledgements

Proctoring in the technique of laparoscopic colonic resection was provided by Mr K. Wedgwood and the study was funded by East Somerset NHS Trust and Somerset Health Authority. P.E. is funded under the NHS Executive South and West Research and Development Support Unit scheme. This study was approved by the East Somerset local research ethics committee.

Surgical treatment of severe duodenal polyposis in familial adenomatous polyposis

C. PENNA, N. BATAILLE, P. BALLADUR, E. TIRET and R. PARC

Department of Digestive Surgery, Hôpital Saint-Antoine, 184 Rue du Faubourg Saint-Antoine, 75 012 Paris, France
Correspondence to: Professor R. Parc

Background Patients with familial adenomatous polyposis (FAP) are at risk for adenomas and cancers in the duodenum but the ideal management of duodenal polyposis remains uncertain.

Methods The outcome of surgical resection was analysed in 18 patients with FAP who had severe duodenal polyposis.

Results Duodenotomy and clearance of duodenal adenomas was performed seven times in six patients. There were two duodenal leaks and, after a mean follow-up of 53 (range 36–72) months, duodenal adenomas recurred in all patients and five had severe polyposis. Pancreatoduodenectomy was performed in seven patients with severe duodenal polyposis. Histology of the specimens revealed two unsuspected duodenal carcinomas at an early stage. After a mean follow-up of 42 months all patients were alive and well, and there was no case of jejunal polyposis. Pancreatoduodenectomy was attempted in five patients with duodenal cancer and only one survived more than 4 years.

Conclusion Surgical excision of duodenal adenomas should be discussed before carcinoma occurs. Surgical polypectomy fails to guarantee a polyp-free duodenum and carries a risk of postoperative complications whereas pancreatoduodenectomy eliminates the risk of duodenal cancer with an acceptable morbidity rate. Pancreatoduodenectomy could be offered to some patients with large or multiple villous duodenal adenomas repeatedly showing severe dysplasia.

Duodenal adenomas develop in most patients with familial adenomatous polyposis (FAP)[1,2] and there is growing evidence to suggest that the adenoma–carcinoma sequence occurs in the upper gastrointestinal tract. Pathological studies of duodenal cancer in FAP have revealed adenomatous tissue in 66 per cent of cases, and adenomas as a component of, or adjacent to, duodenal cancer in 84 per cent[3]. The incidence of periampullary cancer is estimated to be 200–300 times greater than that in the general population[4], and duodenal cancer accounts for the majority of cancer-related deaths after colectomy[5].

Although the natural history of duodenal adenoma is unknown and the reported incidence of duodenal cancer is low (37 (3 per cent) of 1255 registered patients[5]), classification of duodenal polyposis on a five-grade scale based on polyp number, size, histology and severity of dysplasia (*Table 1*) showed that patients with stage IV disease, accounting for about 10 per cent of patients with FAP, are at greatest risk of malignant change[6].

In these cases, endoscopic removal is often impractical because large and sessile polyps cannot be snared and perforation may occur whereas electrocoagulation may cause periampullary scarring and bile duct obstruction or pancreatitis. Therefore, preventive surgery may be indicated for patients who have rapid polyp growth and consistently severe dysplasia.

The aim of this study was to determine the outcome of patients with FAP with severe duodenal polyposis or duodenal cancer in whom a surgical approach had been used and to compare the results of polypectomy by duodenotomy and pancreatoduodenectomy.

Stage 0, 0 points; stage I, 1–4 points; stage II, 5–6 points; stage III, 7–8 points; stage IV, 9–12 points

Patients and methods

Among the 260 patients treated for FAP in this hospital between 1983 and 1996, those who had undergone surgical treatment for duodenal adenoma or adenocarcinoma were identified from the medical records. Data obtained from retrospective review of these records included patient's age and sex, the type of colorectal resection, the findings at each upper gastrointestinal endoscopy session, the type of surgical resection of duodenal adenomas and the subsequent course of each patient regarding postoperative complications, recurrence of duodenal adenomas, bowel function and survival. The severity of duodenal polyposis was classified according to a system previously described by Spigelman *et al.*[1] in which variables that worsen the stage are increasing number, size, villous morphology and degree of dysplasia (*Table 1*). Severe duodenal polyposis was defined by stage IV polyposis with adenomas showing severe dysplasia at two repeated examinations.

Duodenotomy involved a Kocher manoeuvre, longitudinal incision of the second part of the duodenum, removal of larger polyps by a technique of submucosal infiltration and local incision with clearance of the remaining polyps in the duodenum by either excision or diathermy, transverse closure of the duodenal defect by a running one-layer suture of resorbable suture and drainage.

Pancreatoduodenectomy for severe duodenal polyposis was performed with pylorus preservation when the first part of the duodenum was free of polyps and the restorative procedure was a pancreaticogastric anastomosis. When duodenal cancer was suspected before operation or proven, a standard Whipple procedure was performed with pancreatojejunal anastomosis.

Results

Duodenotomy and clearance of duodenal polyps was performed seven times in six patients (five women) with stage IV duodenal polyposis, at a mean age of 40 (range 25–62) years. Some of the results in these patients have been published previously[7]. One patient had a previous coloproctectomy with ileostomy; in the other cases duodenotomy and restorative proctocolectomy with ileal J pouch–anal anastomosis (IPAA) was performed simultaneously. One patient had cholecystectomy on day 5 for acute cholecystitis. Two patients developed a duodenal fistula. One was treated medically and the other, which occurred after repeated duodenotomy, necessitated reoperation for closure and drainage. The histopathology of the resected specimens was similar to that of the preoperative evaluation in all cases. Duodenal adenomas recurred in all patients after 6–36 months. After a mean follow-up of 53 (range 36–72) months all but one patient had stage III or IV duodenal polyposis.

Pancreatoduodenectomy was attempted in 13 patients. Of the five patients with preoperative biopsy-proven duodenal carcinoma, resection was not possible in two cases because of peritoneal carcinomatosis or distal lymph node involvement, and death occurred within 12 months in both cases. The remaining three patients had a Whipple procedure with no perioperative complication. One patient with a tumour restricted to the muscle of the sphincter of Oddi without metastasis to lymph nodes was alive after 9 years of follow-up. The other two died at 17 months from peritoneal carcinomatosis and at 46 months from rectal cancer distal to an ileorectal anastomosis.

In eight patients (four women) with severe duodenal polyposis but without carcinoma on preoperative duodenal biopsy, pancreatoduodenectomy was attempted at a mean age of 54 (range 41–71) years for severe duodenal polyposis. All patients had had a previous colectomy: ileorectal anastomosis in four cases, abdominoperineal resection and ileostomy for stage II rectal cancer 7 years after ileorectal anastomosis in one case and IPAA in three. One patient had stage IV duodenal polyposis with severe dysplasia on a 2-cm indurated adenoma at the first endoscopy when he was 47 years old. The remaining seven patients were followed regularly with upper gastrointestinal endoscopy and progressed from stage 0–II to stage IV in a mean of 10 (range 5–16) years (*Table 2*). Symptoms related to duodenal polyps occurred in three cases: acute oedematous pancreatitis in one and upper gastrointestinal haemorrhage in two. Four patients had had previous endoscopic removal of duodenal adenomas and one had had removal of a large polyp by duodenotomy at the time of restorative proctocolectomy. Endoscopic treatment was not attempted in the other three patients because of the periampullary location of multiple and sessile adenomas. They received sulindac, which failed to stop the progression to stage IV disease in all cases. The presence of abdominal desmoid tumours precluded pancreatoduodenal resection in one patient who was still alive with stage IV polyposis 2 years later.

Pancreatoduodenectomy was performed in three other patients with limited desmoid tumours, but in one case with involvement of the root of the mesentery by the desmoid tumour the bile duct was transected in its lower portion to allow a tension free biliary–enteric anastomosis. In two of the three patients with previous IPAA the jejunal loop was placed behind the mesenteric root to avoid torsion of the mesenteric vessels and then anastomosed to the pylorus. The pylorus was preserved in all but one case in which the first portion of the duodenum was carpeted with polyps. There was no postoperative death.

Table 2 Follow-up data in eight patients with severe duodenal polyposis who had pancreatoduodenectomy

	First endoscopy		Endoscopy before operation							
Patient no.	Age (years)	Stage	Age (years)	Stage	Dysplasia	Operation	Histology of specimen	Postoperative course	Follow-up (months)	Jejunal biopsy
1	38	I	50	IV	Severe	ADT (no resection)	—	—	24	Stage IV, severe dysplasia
2	47	IV	47	IV	Severe	PP, PG	Severe dysplasia	—	108	95 months, no polyps
3	35	II	41	IV	Severe	PP, PG	Severe dysplasia	Pancreatic fistula	50	24 months, no polyps
4	55	0	60	IV	Severe	G, PG	Severe dysplasia	—	36	—

6	39	II	49	IV	Severe	PP, PG	Severe dysplasia	Upper gastrointestinal haemorrhage	24	12 months, no polyps
7	40	I	56	IV	Severe	PP, PG	Invasive carcinoma	—	9	6 months, no polyps
8	63	II	71	IV	Severe	PP, PG	Severe dysplasia	—	36	15 months, no polyps

ADT, abdominal desmoid tumour; PP, pylorus preservation; PG, pancreatogastric anastomosis; G, gastrectomy

The postoperative course was uneventful in five cases, one patient was reoperated on at day 9 for upper gastrointestinal haemorrhage originating from the duodenojejunal anastomosis, and another developed a low-output pancreatic fistula which was treated medically and healed spontaneously by day 17. Histopathological examination of the resected specimens revealed invasive carcinoma in two cases with no muscular invasion. After a mean follow-up of 42 (range 9–108) months all patients were alive and well, although one complained of duodenogastric reflux despite pylorus preservation. In the three patients with IPAA and the three with ileorectal anastomosis, bowel function was not affected by the procedure. The stomach and the jejunal loop were screened at least once in six patients, 6–95 months after the procedure. No gastric or jejunal polyps were found and random biopsies of the jejunal loop were normal.

Discussion

This study shows that duodenotomy and clearance of duodenal polyps was associated with postoperative complications and failed to guarantee a polyp-free duodenum in the long term. Pancreatoduodenectomy satisfactorily cured duodenal polyposis, allowed the complete removal of previously unsuspected duodenal carcinomas, was not associated with considerable morbidity and was feasible after restorative proctocolectomy. When duodenal carcinoma was present, resection was not always feasible and the outcome was poor.

In FAP, the management of multiple and large duodenal adenomas with severe dysplasia and not amenable to endoscopic removal remains controversial. The potential for such lesions to degenerate into carcinoma associated with the difficulties of diagnosis of carcinoma at an early stage despite regular surveillance[8] leads the authors to propose prophylactic surgical excision. Duodenotomy and clearance of duodenal polyps[7] or local excision of the ampulla[8] may considerably reduce the occurrence of malignancy but recurrence is the rule and, despite the potential morbidity of this type of surgery, patients should be regularly and indefinitely followed with upper gastrointestinal endoscopy.

Pancreatoduodenectomy is often seen as a major operation with mortality and morbidity rates unacceptable in the treatment of benign disease. On the other hand, when duodenal carcinoma has developed, the results of pancreatoduodenal resection are disappointing with a mean survival time of 42–57 months after resection of node-negative duodenal cancer and 6–16 months when lymph nodes are involved[9,10]. During the past decade, the postoperative mortality rate associated with pancreatoduodenal resection has decreased markedly. Several authors have reported numerous pancreatoduodenal resections without a death[11,12]. In a series of 108 pancreatoduodenectomies for benign disease, the mortality rate was less than 1 per cent and only two patients required reoperation for a complication, leading the authors to the conclusion that concerns about mortality and morbidity should not prevent an aggressive approach to surgical resection in patients with benign disease[13].

In the management of patients with FAP with severe duodenal polyposis, pylorus preservation and pancreatogastric anastomosis seems to present several advantages over the classical Whipple procedure. Pylorus preservation avoids gastric resection and procures a better functional outcome with fewer cases of dumping, diarrhoea and marginal ulceration[14]. The preserved pylorus reduces bile reflux into the stomach, which had been incriminated in gastric adenoma formation[15]. Pancreatogastric anastomosis is a simple reconstruction method[16] which offers several potential advantages including an easy tension-free anastomosis due to the natural disposition of the pancreas on the posterior wall of the stomach, a well vascularized anastomosis with the thick gastric wall with its excellent blood supply, a significant distance between biliary and pancreatic anastomoses obviating the deleterious effects of leakage of one on the other, and protection against anastomotic ulceration by alkaline pancreatic secretions[17,18]. Preservation of the entire stomach with an end-to-end duodenojejunal anastomosis and a choledochojejunostomy constructed 10 cm downstream[19] facilitates endoscopic screening of the remaining jejunum receiving bile outflow and helps to preserve bowel function after proctocolectomy in avoiding a blind-loop jejunostomy.

Although duodenal adenomas are seen in nearly all patients with FAP, the risk of developing duodenal carcinoma remains low. In the future, new treatments under evaluation such as photodynamic laser therapy and use of non-steroidal anti-inflammatory drugs may help to prevent adenoma formation or transformation[20]. However, for those in whom polyps are growing rapidly and when severe dysplasia is found at several histological examinations, surgical resection should be proposed before carcinoma develops. In these rare cases, pancreatoduodenal resection offers several advantages over polyp excision by duodenotomy and can be achieved with a low morbidity rate in experienced hands.

Background Triple assessment is the standard method of assessing symptomatic breast lumps. There is an accepted format for reporting cytology but not for the reporting of mammograms or breast ultrasonographic images. This study describes a scoring system for reporting breast imaging methods.

Methods Patients with symptomatic breast lumps seen during 1 year were included. All patients underwent triple assessment. Imaging studies were reported using a grading system from 1 to 5. The results of triple assessment were compared with the final histology.

Results Some 127 women had both mammography and ultrasonographic imaging; the final grade was identical in 60 per cent. The positive predictive value of imaging reported as grade 5 or 4 combined with cytology of C5 or C4 was 100 per cent. All lesions with C3 cytology and benign imaging were benign on histological examination whereas if a C3 grade was combined with imaging grade 5 or 4, all the lesions were malignant.

Conclusion Combining the imaging grade with the results of aspiration cytology and clinical examination often predicts the final histology in patients with breast disease.

Clinical examination, radiological imaging and fine-needle aspiration cytology (FNAC) has become the approved method of assessing patients with symptomatic breast lumps[1–4]. The interpretation of cytological smears has become standard as described in the National Health Service (NHS) Breast Screening Programme guidelines for cytology procedures[5]. Similar standard prospectively evaluated categories for reporting of mammograms or breast ultrasonographic images do not currently exist. In some cases it may be very difficult for a clinician to assess the degree of radiological suspicion based on a written report, especially if the appearances are indeterminate. This study analyses the use of grades similar to those described for cytological analysis to report mammograms and ultrasonographic images.

Patients and methods

Some 306 consecutive new patients who presented over 12 months (September 1995 to August 1996) to the breast clinic at this hospital and subsequently underwent surgery were included in the study. Histological confirmation was obtained in all cases. The patients all underwent clinical examination and FNAC. Mammography was the imaging method in symptomatic women over 35 years. Patients under 35 years had high-frequency ultrasonography unless there was a strong clinical suspicion of cancer in which case a mammogram was also obtained. Most imaging was done on the day of presentation in the breast clinic; the radiologists were aware of the clinical findings but not the cytology results. The preoperative presumptive diagnosis was recorded.

Imaging

Mammography was carried out using a dedicated mammographic unit (International General Electric, Slough, UK) and film screen combination. Standard craniocaudal and lateral oblique views were taken, with further paddle magnification views in some cases before a final report was given. A Hitachi EUB 415 scanner (Wellingborough, UK) was used for ultrasonographic examination with a 7·5-MHz high-frequency transducer. The mammograms and ultrasonographic images were reported by one of three specialist breast radiologists. When ultrasonography was used to supplement mammography or vice versa, the radiologist was not blinded to the original imaging result. The grade for each imaging investigation was recorded independently using a scale M1–5 (mammography) or U1–5 (ultrasonography) (*Table 1*). If the findings on imaging were inconsistent, the most suspicious feature determined the final grade. Any additional mammographic views performed were included in the final grading.

Cytology

FNAC of palpable lesions was performed using a 21- or 23-G needle attached to a 10-ml syringe. Any nipple discharge was sent for cytology. FNAC of impalpable lesions was done using stereotactic or ultrasonographic control. The smears were air dried and fixed in alcohol, and then stained by both May–Gruenwald Giemsa and Papanicolaou techniques. A cytological grade was assigned using a scale C1–C5.

Analysis

The positive predictive values of abnormal cytology (C3–C5) and imaging were calculated according to published guidelines[5]. The sensitivity and specificity were also calculated. Atypical or indeterminate reports (grade 3) were evaluated both as a positive finding of malignancy and as a benign finding, resulting in two sensitivity and specificity rates for each modality of triple assessment. Inadequate aspirates were excluded from the sensitivity and specificity calculations for FNAC. Statistical analyses were carried out using Fisher's exact probability test.

Results

During the study, 311 breast lesions in 306 patients were excised; 150 were malignant (benign to malignant ratio 1:1). This excluded operations for nipple discharge. Fifty patients had lesions detected by mammographic screening; 47 from the NHS Breast Screening Programme and three from the Family History Clinic. There were 261 symptomatic lesions, including 230 palpable lumps and 16 patients with nipple discharge who underwent micro-

Paper accepted 10 August 1997

Table 1 Grading of imaging reports

Grade	Degree of suspicion	Mammographic appearance	Ultrasonographic appearance
1	Normal appearance	No abnormality seen	No abnormality seen
2	Consistent with a benign lesion	Scar Well circumscribed mass of relatively low density possibly with halo and/or popcorn calcification Multiple well circumscribed rounded masses Lesion containing fat Ring or microcystic or diffuse bilateral calcification	Scar, implant, abscess, duct ectasia, haematoma Unilocular simple cyst Homogeneous well defined oval solid mass with horizontal orientation pushing surrounding tissues
3	Atypical or indeterminate appearance but probably benign	Distortion, possible positional shadow Localized cluster of round calcifications Solitary round mass of intermediate density	Cyst with solid elements or irregular wall Solid mass not clearly horizontally orientated Solid mass with a lobulated margin
4	Suspicious of malignancy	Ill defined or irregular dense mass Spiculated lesion without central mass Localized cluster of fine, punctate or granular calcification Lymphadenopathy alone	Ill defined heterogeneous mass Distortion with no central mass Lymphadenopathy alone
5	Consistent with malignancy	Spiculated lesion with central mass possibly with microcalcification Comedo calcification Thickened skin without a benign explanation All of above possibly with lymphadenopathy	Irregular hypoechoic mass interrupting breast trabeculae possibly with or without any of the following features: distortion, distal shadowing, vertical orientation and/or lymphadenopathy

When findings on imaging were mixed, the most suspicious finding determined the grade

Table 2 Sensitivity and specificity of the different modalities as part of the triple assessment

	Grades 3–5	Grades 4 and 5 only
FNAC (*n* = 252)		
Sensitivity (%)	98	94
Specificity (%)	83	95
Mammography (*n* = 249)		
Sensitivity (%)	92	83
Specificity (%)	78	91
Ultrasonography (*n* = 178)		
Sensitivity (%)	82	75
Specificity (%)	79	93

FNAC, fine-needle aspiration cytology

Table 3 Positive predictive value for malignancy of abnormal cytology, mammography and ultrasonography

	Positive predictive value (%)		
Investigation	Grade 3	Grade 4	Grade 5
Cytology (*n* = 146)	25	82	99
Mammography (*n* = 155)	48	74	99
Ultrasonography (*n* = 78)	25	70	94

dochectomy. The remainder presented with mastalgia or nipple symptoms but an incidental impalpable abnormality was detected radiologically and then excised. The sensitivity (proportion of cancers correctly identified) and the specificity (proportion of benign lesions correctly identified) were calculated for each modality of the triple assessment (*Table 2*).

Mammography

Mammography was performed in 249 patients. Seven cancers were reported as M1 and five as M2 giving an overall false-negative rate of 9 per cent. The false-negative rate was higher in patients aged less than 50 years (24 *versus* 4 per cent; P = 0·002). An indeterminate or M3 mammogram report had a positive predictive value for cancer of 48 per cent (*Table 3*). When M3 mammography was included as a positive finding, the sensitivity of mammography was 92 per cent overall (*Table 2*). Mammography was more sensitive in patients aged over 50 years (96 *versus* 77 per cent; *P* = 0·003), even if screen-detected lesions were excluded. Five women aged under 35 years with cancer had mammography. All lesions were reported as atypical or suspicious of malignancy; in one the ultrasonographic appearance was benign. Only one benign lesion, a radial scar, was reported as M5.

Ultrasonographic imaging

Fifty-one women (median age 28 years) had an ultrasonographic scan as their only imaging assessment; 48 lesions (94 per cent) were reported as normal or benign. If combined with a C2 FNAC result, all were benign on excision biopsy. Overall 178 women had ultrasonography. Five lesions reported as U1 were malignant, all of which were impalpable. If, however, a palpable lesion appeared normal on ultrasonography, it was benign. Seven cancers were reported as U2, of which three were impalpable. Overall the false-negative rate for ultrasonography was 18 per cent. Eight benign lesions were reported as U5 or U4. The histology included radial scars, fat necrosis and a phyllodes tumour. In all these cases the cytology was benign. Eight women with false-negative mammograms were assessed by ultrasonography, five of whom had lesions with malignant or suspicious features; two were reported as U3 and one as U2. Ultrasonographic imaging also helped to confirm the presence of a malignant lesion in five patients in whom the mammographic appearance was indeterminate (M3); however, a normal or benign ultrasonographic appearance did not exclude a malignancy when associated with an M3 mammogram. One hundred and twenty-seven women had both mammography and ultrasonography. The final grade given in the report was identical in 76 (60 per cent) and was identical or similar, i.e. M5 U4 or M5 U5, in 87 (69 per cent).

Cytology

FNAC was not performed in 16 patients for a variety of technical reasons such as the presence of an implant. The overall inadequate or C1 rate was 43 of 295 (15 per cent); 15 (10 per cent) of the 143 cancers on which FNAC was performed had inadequate (C1) cytology. A phyllodes tumour gave rise to the only false-positive C5 result. The smears were highly cellular and there was relative discohesion of the epithelial component. In this patient, imaging was indeterminate (M3, U3). Three cancers were reported as C2 giving a false-negative rate of 2 per cent.

Scoring system

Table 4 shows the relationship of the FNAC and imaging results with the final histology. If a patient had both methods of imaging, each report was regarded separately and the most suspicious used. Excluded from this *Table* were 43 lesions with C1 cytology and 21 lesions for which there was no imaging or FNAC result. The positive predictive values of C5 and C4 cytology were 99 and 82 per cent respectively. All 103 lesions graded C5 or C4 by FNAC and grade 4 or 5 by mammography or ultrasonography were malignant. A C3 grade on FNAC had a positive predictive value for cancer of 25 per cent. When combined with a benign imaging result, the positive predictive value was 0 per cent, compared with 100 per cent when combined with suspicious or malignant imaging ($P = 0 \cdot 0003$). All lesions of imaging grade 3 when associated with C2 cytology were benign ($n = 14$). Likewise, all lesions with C2 cytology and benign or normal appearances on imaging ($n = 79$) were benign when excised.

Table 4 Relationship between fine-needle aspiration cytology (C1–5) and mammography (M1–5) and/or ultrasonographic imaging (U1–5) grade and final histology

Combined cytology and imaging (M/U) grade	Benign	Cancer	Positive predictive value (%)
Benign			
C3 and M/U 1 or 2	12	0	0
C2 and M/U 1, 2 or 3	93	0	0
Indeterminate			
C5 + C4 and M/U 1, 2 or 3	6	13	68
C4 and M/U 4	0	5	100
C2 and M/U 4 or 5	9	3	25
C3 and M/U 4 or 5	0	5	100
C3 and M/U 3	3	0	0
Malignant			
C5 and M/U 4 or 5	0	81	100
C4 and M/U 5	0	17	100

Discussion

Clinical examination, FNAC and imaging (mammography and/or ultrasonography) combined as the triple assessment for breast abnormalities has a sensitivity of greater than 99 per cent if all investigations concur[3]. When there are discrepancies a definitive diagnosis cannot be made and excision of the lesion is often recommended[3,6]. The scoring system described here resulted in sensitivity and specificity rates comparable to previously published data[3,7]. By combining the imaging grades with the FNAC results, the final histology can be predicted in the majority of cases (*Table 4*), potentially reducing the need for biopsy.

There is still a widespread tendency amongst surgeons to remove all discrete lumps in women aged over 35 years, despite a normal triple assessment, because of the small but significant false-negative rate. All 79 lesions in this study with benign cytology and imaging were benign on histological examination. Six were clinically suspicious but the remainder were thought to be benign on examination; 39 (53 per cent) were in women aged over 35 years. Had these lesions not been excised the rate of benign biopsy could have been reduced by 45 per cent and the benign to malignant ratio to 1:2.

Lesions with atypical cytology (C3), when associated with benign imaging were all benign on excision; similarly lumps with atypical imaging (M3 or U3), when associated with benign cytology were all found to be benign (*Table 4*). This indicates that if a patient does not wish surgery and the lesion is clinically benign, conservative treatment is safe, providing follow-up is adequate with repeat FNAC or imaging as appropriate.

A C5 or C4 result on FNAC combined with suspicious or malignant imaging (M4–5 and/or U4–5) had a positive predictive value for cancer of 100 per cent, suggesting that definitive treatment can be planned for clinically suspicious lumps with these results (*Table 4*). If the FNAC result is C5 or C4 but the imaging indicates a benign lesion, or vice versa, then a core biopsy should be performed or the lump excised.

Over two-thirds of the patients (69 per cent) who had both mammography and ultrasonography had identical or similarly graded reports for both imaging methods. This demonstrates a close correlation between the two techniques but also suggests that in the majority of cases ultrasonographic imaging in addition to mammography may not be necessary, especially if the mammogram is reported as definitely malignant (M5) or definitely benign (M2).

In conclusion, this imaging scoring system accurately relays the radiologist's suspicions to the clinician. The combination of the imaging grade with the results of aspiration cytology and clinical examination helps predict the final histology. The value of this scoring system needs to be confirmed in larger prospective studies.

Effect of graft reperfusion on intracellular calcium levels in mononuclear leucocytes during human orthotopic liver transplantation

S. M. ENRIGHT, R. SRINIVASA* and M. C. BELLAMY*

*Academic Unit of Anaesthesia and *Departments of Anaesthesia and Intensive Care, St James's University Hospital, Leeds, UK*
Correspondence to: Dr M. C. Bellamy, Department of Anaesthesia, St James's University Hospital, Beckett Street, Leeds LS9 7TF, UK

Background Orthotopic liver transplantation (OLT) is accompanied by local and systemic manifestations of the ischaemia–reperfusion syndrome. Local effects are mediated in part through changes in intracellular calcium levels in Kupffer cells. Arachidonic acid metabolites mediate increases in intracellular calcium concentration and thus potentiate the effect of free radicals. This study was carried out to characterize white blood cell (WBC) calcium changes as a mediator for white cell activation in human OLT.

Methods Twenty consecutive patients had OLT using standard surgery and anaesthesia techniques. Blood samples were drawn for estimation of WBC cytosolic calcium content at induction of anaesthesia, 5 min before graft reperfusion and 15 min after reperfusion. The rate of rise in intracellular calcium concentration after the addition of a calcium chloride 1 mmol l^{-1} solution to the extracellular milieu was used as an estimate of membrane calcium permeability.

Results Both extracellular ($P = 0{\cdot}0002$) and intracellular ($P = 0{\cdot}0008$) calcium concentrations rose with time. However, at no time was there a correlation between extracellular and intracellular calcium levels or rate of calcium influx ($r^2 = 0{\cdot}002$, $P = 0{\cdot}78$). There was a significant increase in intracellular calcium concentration ($P = 0{\cdot}0008$) and in the rate of rise of intracellular calcium levels ($P = 0{\cdot}0009$) after reperfusion.

Conclusion There was a significant increase in circulating monocyte membrane permeability for calcium and cytosolic calcium concentration following reperfusion in human OLT. This was independent of extracellular calcium concentration. These results are consistent with WBC activation by reperfusion and could be implicated in the systemic reperfusion syndrome seen in OLT in humans.

Orthotopic liver transplantation (OLT) is associated with a reperfusion syndrome[1], which occurs soon after revascularization of the ischaemic donor graft. Post-reperfusion syndrome is defined[1] as a reduction in mean arterial pressure of 30 per cent occurring within 5 min of graft reperfusion and persisting for at least 1 min. This may be cytokine mediated and is associated with changes in arachidonic acid metabolism. Hypotension associated with a low systemic vascular resistance may persist for 1 h or more. Reperfusion syndromes are thought to be mediated via intracellular calcium influx resulting in raised cytosolic calcium concentration[2-4]. Previous studies have focused on intracellular calcium concentration change in graft cells following reperfusion. However, the reperfusion syndrome exhibits systemic manifestations. Therefore, in this study the extent to which reperfusion of donor liver graft is associated with changes in intracellular calcium concentration in mononuclear leucocytes was characterized, reflecting the systemic nature of the reperfusion syndrome.

Patients and methods

The study was approved by the local research ethics committee and informed consent obtained. Twenty consecutive patients who had elective OLT were studied. All the patients were anaesthetized using an opioid–volatile agent sequence with venovenous bypass according to a standard technique[5]. Non-invasive monitoring was established and anaesthesia induced with midazolam 0·1 mg kg^{-1}, alfentanil 0·1 mg kg^{-1} and atracurium 0·6 mg kg^{-1}. Following tracheal intubation the lungs were ventilated to normocapnia with desflurane in oxygen-enriched air. Anaesthesia was supplemented[6] with alfentanil at 0·05 mg kg^{-1} h^{-1} and muscle relaxation facilitated with atracurium 0·5 mg kg^{-1} h^{-1}. Further monitoring included a triple-lumen central venous line, mixed venous oximetric right-ejection fraction pulmonary artery flotation catheter, and a radial arterial line. An 18-Fr percutaneous cardiac bypass cannula was inserted into the internal jugular vein and connected to a rapid infusion system (Hemonetics, Braintree, Massachusetts, USA)[7]. A further 18-Fr bypass cannula was placed into the right femoral vein to allow venovenous bypass[8]. Dopamine 3 μg kg^{-1} min^{-1} and 4 per cent glucose in 0·18 per cent saline infusions (1 ml kg^{-1} h^{-1}) were commenced and continued after operation according to the authors' protocol[5]. Standard surgical technique was used[9] with an out-of-ice to reperfusion time of less than 1 h in all cases. Reperfusion sequence involved removal of the upper caval clamp, portal vein reperfusion, removal of the lower caval clamp and subsequent hepatic arterial anastomosis. No drugs that might have affected extracellular calcium levels were given between stages I and II; between stages II and III, calcium supplements were used to maintain serum ionized calcium concentration between 0·85 and 1·4 mmol l^{-1} and the dose was recorded. Immunosuppressant therapy was withheld until after surgery.

Blood samples (10 ml) for determination of intracellular calcium concentration ($[Ca^{2+}]_i$) were drawn into lithium–heparin bottles at three time points: induction of anaesthesia (stage I), 5 min before reperfusion of the graft (stage II) and 15 min after reperfusion (stage III). The anticoagulated blood was mixed with equal volumes of white blood cell culture medium RPMI 1640 (Sigma Diagnostics, St Louis, Missouri, USA)[10] at pH 7·3. The blood mixture was then layered on to Histopaque-1077 (Sigma Diagnostics), which is a solution of polysucrose and sodium diatrizoate, and centrifuged at 700*g* for 30 min at room temperature. During centrifugation, erythrocytes and granulocytes are aggregated by the polysucrose and sediment rapidly, but lymphocytes and other mononuclear cells remain at the

Paper accepted 21 October 1997

plasma–Histopaque interface. The mononuclear layer was then collected before $[\mathrm{Ca}^{2+}]_i$ determination.

$[\mathrm{Ca}^{2+}]_i$ was measured using the fluorescent dye, Fura-2, employing established methods[11]. Fura-2 is a fluorescent indicator whose peak emission wavelength changes from 380 to 340 nm when it is bound to Ca^{2+} in a 1 : 1 ratio. The cell-permeant acetoxymethylester form of Fura-2, Fura-2AM (Sigma Diagnostics), was incubated with the cells at a concentration of 1 mmol l^{-1} for 30 min at 37°C. After incubation, cells were collected by centrifugation and washed twice with RPMI 1640 solution. After the final wash, cells were resuspended in RPMI 1640 before determination of $[\mathrm{Ca}^{2+}]_i$.

The fluorescence measurements were performed at 25°C using a luminescence spectrophotometer (LS50; Perkin Elmer, Beaconsfield, UK). The excitation wavelengths were 340 and 380 nm, and the emission wavelength was 510 nm. Emission intensities after alternate excitation at 340 and 380 nm were plotted as a 340/380 ratio (R), and an average of 30 readings over 60 s was obtained for each sample. A value for the maximum ratio ($\mathrm{R}_{\max}$) was obtained by adding calcium chloride 1 mmol l^{-1} to the milieu, then disrupting the cells using the ionophore Ionomycin (ICN Biomedicals, Thame, UK), the ratio being that for completely bound Fura-2. The minimum ratio ($\mathrm{R}_{\min}$) was then derived by adding manganese chloride 1 mmol l^{-1}, which displaces Ca^{2+} from Fura-2 and gives a ratio value for completely unbound probe. $[\mathrm{Ca}^{2+}]_i$ was calculated using the Grynkiewicz formula[11]. Following addition of calcium chloride to the extracellular milieu, the initial rate of rise in $[\mathrm{Ca}^{2+}]_i$ was recorded. This was compared between cells collected before and after graft reperfusion.

Plasma ionized (extracellular) Ca^{2+} levels were also measured at the same time as samples for $[\mathrm{Ca}^{2+}]_i$ determination, using a Model 288 blood gas system (Ciba-Corning, Medfield, Massachusetts, USA). All measurements were performed in duplicate to avoid idiosyncratic errors, and mean values were recorded.

Statistical analysis

Results are expressed as median (interquartile range). Determinations of $[\mathrm{Ca}^{2+}]_i$ at induction and before and after reperfusion were compared using Friedman's two-way analysis of variance by rank for non-parametric data. Specific differences between the time points were investigated using a Bonferroni-corrected Wilcoxon signed-rank matched-pairs test. The rate of rise of $[\mathrm{Ca}^{2+}]_i$ before and after reperfusion was compared with the Wilcoxon signed-rank matched-pairs test. Correlations between intracellular and extracellular calcium concentration, and rate of rise of intracellular calcium content, were tested by Pearson's linear regression.

Results

The patients were seven men and 13 women of mean age 49 (range 42–50) years. Their diagnoses were: primary biliary cirrhosis (five patients), seronegative hepatitis (three), primary sclerosing cholangitis (one), lupus (one), chronic rejection (one), alcoholic cirrhosis (three), hepatitis B (one) and cryptogenic cirrhosis (five). Graft total ischaemic times were 592 (540–710) min. Total calcium administered to maintain extracellular calcium concentration within the range 0·85–1·4 mmol l^{-1} was 22·5 (20–30) mmol.

Intracellular and serum (extracellular) ionized calcium concentrations and the rate of rise of intracellular calcium content in the experimental rig (calcium influx) are detailed in *Table 1*. Both extracellular ($P = 0·0002$) and intracellular ($P = 0·0008$) calcium concentrations rose with time. However, at no time was there a correlation between extracellular and intracellular calcium concentration (*Fig. 1*) or rate of calcium influx ($r^2 = 0·002$, $P = 0·78$).

Table 1 Extracellular and intracellular free calcium concentrations and rate of rise of cytosolic calcium level

	Baseline (I)	Before reperfusion (II)	After reperfusion (III)
Extracellular calcium (mmol l^{-1})	1·06 (0·92–1·15)	1·14 (0·9–1·24)*	1·42 (1·31–1·62)
Intracellular calcium (nmol l^{-1})	10·8 (6·4–23·1)	16·7 (8·2–27·0)	24·9 (16·2–50·0)†
Calcium influx (nmol $\mathrm{l}^{-1}\,\mathrm{s}^{-1}$)	—	7·4 (4·6–13·5)	8·9 (5·7–33·3)‡

Values are median (interquartile range). *$P = 0·0002$ *versus* baseline and postreperfusion; †$P = 0·0008$, ‡$P = 0·0009$ *versus* before reperfusion (Bonferroni-corrected Wilcoxon signed rank test)

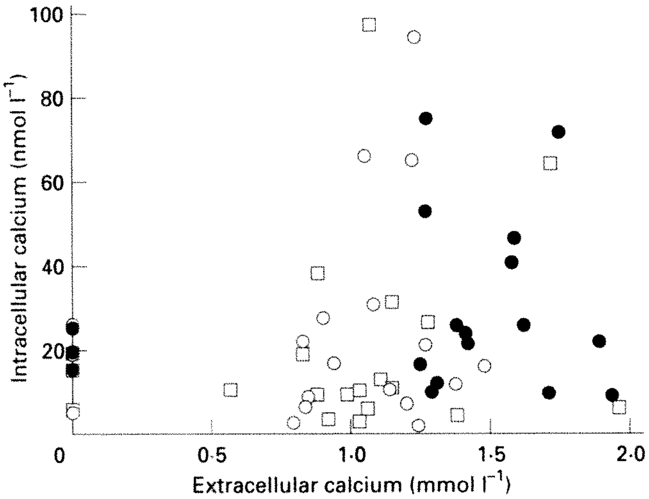

Fig. 1 Intracellular *versus* extracellular calcium concentrations. No correlation was seen between extracellular and intracellular calcium levels at the three time points: □, baseline (I) ($r^2 = 0·02$, $P = 0·57$); ○, before reperfusion (II) ($r^2 = 0·001$, $P = 0·89$); ●, after reperfusion (III) ($r^2 = 0·04$, $P = 0·44$)

There was an increase in median $[\mathrm{Ca}^{2+}]_i$ between times I and II but this was not statistically significant ($P = 0·46$). There was a significant increase in $[\mathrm{Ca}^{2+}]_i$ ($P = 0·0008$) and rate of rise of $[\mathrm{Ca}^{2+}]_i$ ($P = 0·0009$) after reperfusion. A correlation was observed between $[\mathrm{Ca}^{2+}]_i$ and rate of influx ($r^2 = 0·42$, $P < 0·001$) (*Fig. 2*). Ischaemic time was not a predictor for postreperfusion $[\mathrm{Ca}^{2+}]_i$ ($P = 0·84$). There was a trend, which was not statistically significant, for patients with a long graft ischaemic time to show a greater rise in $[\mathrm{Ca}^{2+}]_i$ between times II and III ($r^2 = 0·26$, $P = 0·094$).

Discussion

In these patients undergoing elective liver transplantation, graft reperfusion was associated with a significant rise in $[\mathrm{Ca}^{2+}]_i$ in mononuclear leucocytes. Coincidentally an increase in serum ionized (extracellular) calcium concentration was observed during the operation. This probably related to calcium administration as part of the anaesthetic technique[12]. The increase in $[\mathrm{Ca}^{2+}]_i$ did not appear to correlate with changes in serum ionized calcium level. However, when postreperfusion cells were

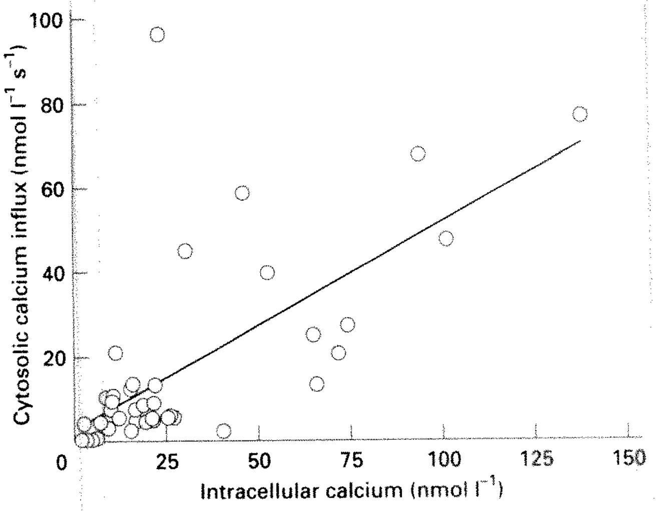

Fig. 2 Correlation between intracellular calcium concentration after reperfusion and cytosolic calcium influx under experimental conditions ($r^2 = 0{\cdot}42$, $P < 0{\cdot}001$)

compared with prereperfusion cells, they not only had a higher cytosolic calcium level, but in the test rig showed a greater rate of increase of $[Ca^{2+}]_i$ when the Ca^{2+} concentration in the test milieu was varied. Small changes in membrane calcium influx could lead to increased mobilization of intracellular calcium stores and hence a substantial increase in cytosolic free calcium.

An increase in $[Ca^{2+}]_i$ has been implicated in several models of ischaemia–reperfusion injury[2–4,13]. The mechanisms may include complex changes in intracellular activation of the phospholipase system and an increase in membrane calcium permeability, as dihydropyridine-type calcium channel antagonists block the increase in $[Ca^{2+}]_i$ following ischaemia–reperfusion injury in the hepatic Kupffer cell[14]. There is circumstantial evidence that this may also be true of the circulating monocyte[15,16].

The reperfusion syndrome in liver transplantation is well recognized[1], occurring to a significant extent in nearly every transplant, as reflected by high serum transaminase levels in the first few days after operation. In the worst cases this can lead to primary graft failure and death[17].

Reperfusion syndrome is thought to begin as a local effect due to Kupffer cell activation in the graft[18]. Storage of donor liver graft with calcium channel blockers reduces Kupffer cell $[Ca^{2+}]_i$ and improves graft survival[19].

The local effects are accompanied by a systemic disorder, involving release of inflammatory mediators[20] and increased circulating levels of arachidonic acid and its derivatives[21]. Arachidonate increases $[Ca^{2+}]_i$ in isolated perfused Kupffer cells in a dose-dependent manner[22]. In another recent study[23], primary cultures of rat Kupffer cells liberated significant amounts of prostaglandin (PG) D_2, PGE_2 and thromboxane (measured as thromboxane B_2) when exposed to reoxygenation after 4 h of hypoxia. Raised prostanoid synthesis was preceded by increased $[Ca^{2+}]_i$.

In the present study it was demonstrated that the increased $[Ca^{2+}]_i$ following reperfusion of the graft was not localized to Kupffer cells, but seen systemically in other cell populations within the immune system. This is consistent with previous findings of systemic changes in arachidonic acid metabolism, autacoid and adhesion molecule expression[20,21]. Calcium is an important intracellular messenger involved in signal transduction and white cell activation. It is proposed that changes in $[Ca^{2+}]_i$ in mononuclear leucocytes are implicated in the systemic immune response seen following liver graft reperfusion in humans.

Preoperative decompression of an obstructed biliary tree does not increase the incidence of postoperative sepsis

A. M. Isla, A. K. Kakkar, R. C. N. Williamson, *HPB Unit, Department of Surgery, Hammersmith Hospital, Du Cane Road, London W12 0NN, UK*

Aim To assess the incidence of infected bile in patients with preoperative biliary decompression and its role in the development of septic complications and biliary fistula after preoperative drainage of the bile duct.

Methods A total of 128 patients (81 men, 47 women) underwent hepaticojejunostomy Roux-en-Y with or without resection of the pancreatic head for either benign disease ($n=46$) or some type of pancreatic or periampullary carcinoma ($n=82$). Preoperative biliary decompression was carried out in 63 patients by the endoscopic ($n=45$), transhepatic ($n=11$) or surgical ($n=7$) route; 65 had no such drainage. Bile cultures were obtained from the bile duct at operation in every case. Operations were performed under broad-spectrum antibiotic cover.

Results Positive cultures were obtained in 55 of 63 patients with preoperative drainage as opposed to 18 of 65 patients without drainage ($P=0{\cdot}0001$). A median of two different organisms (range 1–3) were grown (coliforms 37, enterococcus 16, pseudomonas 8), especially in patients with an indwelling stent. However, the presence or absence of bacterobilia did not affect the incidence of postoperative septic complications (21 *versus* 22 per cent, $P=0{\cdot}9$, or 12 *versus* 13 per cent if chest infection is excluded) nor yet the incidence of anastomotic biliary leakage (5·7 *versus* 7 per cent, $P=10$).

Conclusion Although preoperative biliary decompression nearly always contaminates the biliary tree, it does not increase the risk of postoperative sepsis or biliary fistula in the presence of antibiotic prophylaxis.

Laparoscopic cholecystectomy under epidural anaesthesia in patients with chronic respiratory disease

K. G. Pursnani, Y. Bazza, M. Calleja*, M. M. Mughal, *Department of Surgery and *Anaesthesia, Chorley and South Ribble District General Hospital, Preston Road, Chorley PR7 1PP, UK*

Aim Laparoscopic cholecystectomy (LC) has become firm established as the procedure of choice for gallstone disease that usually necessitates general anaesthesia and endotracheal intubation to prevent aspiration and respiratory embarrassment secondary to the induction of pneumoperitoneum. There is a paucity of data in the literature on the procedure being performed under regional (epidural) anaesthesia, especially in patients with significant pulmonary disease who are deemed high risk for general anaesthesia. This report describes preliminary experience with LC using epidural anaesthesia in patients with chronic obstructive pulmonary disease (COPD).

Methods LC was performed in six patients (one man, 5 women), median age 56 (range 38–74) years, under epidural anaesthesia over an 8-month period. All patients were American Society of Anesthesiologists grade 3 or 4 and the mean FEV_1/FVC was 0·52 (range 0·4–0·68), due to chronic asthma (two) and COPD (four). They were admitted 1 day before surgery for pulmonary function tests, nebuliser and chest physiotherapy. An epidural catheter was introduced at T10/11 intervertebral space and a bolus of 0·5 per cent bupivacaine was administered. Depending on the patient's pain threshold and the segmental level of analgesia achieved, incremental doses of 2 ml of 0·5 per cent bupivacaine along with boluses of intravenous 100 mcg Fentanyl were given to each patient. The patients were breathing spontaneously, no nasogastric tube was inserted and the pneumoperitoneum pressure was limited to 10 mmHg. LC was performed using a standard technique.

Results All patients tolerated the procedure well and made an uneventful postoperative recovery. Median operating time was 50 min and mean length of hospital stay was 2·5 (range 2–4) days. The epidural catheter was removed the morning after operation and only one patient required postoperative opioid analgesia. Two patients complained of persistent shoulder-tip pain during surgery and required intraoperative analgesia. There was no change in the patients' cardiorespiratory status including pO_2 and pCO_2, and no complications occurred either intraoperatively or postoperatively.

Conclusions LC can be performed safely under epidural anaesthesia in patients with severe COPD. Intraoperative shoulder-tip or abdominal pain does not seem to be a major deterrent and can be controlled effectively with small doses of opioid analgesia

Background The relationship of the pH of oesophageal refluxate and its pepsin content to injury of oesophageal mucosa remains unclear. A study was made of the earliest morphological alterations in the oesophageal mucosa secondary to varying concentrations of hydrochloric acid with or without pepsin.

Methods Adult cats had varying concentrations of acid with and without 1 per cent porcine pepsin infused into the oesophagus through a paediatric feeding tube placed 5 cm above the oesophagogastric junction at a rate of 1 ml/min for 30 min. At autopsy 24 h later, the oesophagus was removed intact and scored by an expanded modification of a previously published histopathological scoring system. This included estimates of the intensity and distribution of four morphological features: basal cell hyperplasia (BCH), intraepithelial leucocytes (IELs), subepithelial leucocytes and ulcers. Each of these four categories was scored from 0 to 4, with a maximum injury score of 16.

Results Mean(s.e.m.) scores were as follows: pH 1, 15·0(1·0); pH 1 with pepsin, 13·3(1·4); pH 2, 15·3(0·7); pH 2 with pepsin, 11·7(1·1); pH 3, 1·8(1·6); pH 3 with pepsin, 3·7(1·9); pH 4 with or without pepsin, 0·6(0·2). Differences between pH 3 and 4 *versus* pH 1 and 2 were significant ($P < 0·05$).

Conclusion Injury to the oesophagus is more dependent on the pH of refluxate than on the presence of pepsin. Peptic injury appears to occur at a critical threshold of acid burden ($pH < 3$) as opposed to a graded level of injury based on a pH scale.

For decades the pathophysiology of reflux oesophagitis has been elusive. Although gastro-oesophageal reflux disease (GORD) is the most common upper gastrointestinal disease in the Western world, only a small proportion of the population at risk develops reflux oesophagitis and even fewer demonstrate evidence of macroscopic disease[1]. Many mechanisms of defence act as important deterrents to GORD, all of which in combination maintain a stable milieu within the distal oesophagus and help to prevent reflux injury[2].

In vivo studies in animals have demonstrated that not only acid but also pepsin, bile and pancreatic enzymes (as components of gastroduodenal contents) can induce varying degrees of oesophagitis independently[3–7]. Separation of the roles of acid and pepsin in the production of oesophagitis is difficult because pepsin is active only in an acid environment. Although the presence of acid with or without pepsin remains the *sine qua non* for the development of oesophagitis, the precise relationship of the pH of refluxate to mucosal injury remains unclear. The ulcerogenic potentials of acid and pepsin have been described previously[8,9]; however, there is a paucity of data available on the quantitative evaluation of the effect of varying concentrations of acid to induce oesophagitis. These experiments were designed to quantitate the earliest morphological alterations in the oesophageal mucosa secondary to infusions of different concentrations of hydrochloric acid with and without pepsin.

Materials and methods

Adult cats weighing 3–5 kg were studied. Water and food were permitted *ad libitum* and the animals were not fasted before infusion. Anaesthesia was induced with a combination of ketamine hydrochloride 15 mg/kg and acepromazine 0·2 mg/kg administered intramuscularly. All cats underwent upper endoscopy (Olympus GIF-X20 Endoscope; Olympus, Tokyo, Japan) before infusion, to exclude any gross abnormality of the oesophageal mucosa and also to locate the oesophagogastric junction. The animals were positioned lying on their left side with their head elevated at a slight angle (10–15°). A Harvard infusion pump was used to deliver hydrochloric acid at a rate of 1·0 ml/min through a paediatric feeding tube placed 5 cm above the endoscopically located oesophagogastric junction. Varying pH concentrations of hydrochloric acid (pH 1 to pH 4) with and without 1 per cent porcine pepsin (Sigma Chemicals, St Louis, Missouri, USA) were infused in random order for 30 min in different animals on different experimental days. Most of the authors' previous work studying acute oesophagitis in a feline model has been done using either 0·8 or 1 per cent pepsin. Because human gastric juice normally contains 1500–2000 units/ml of pepsin and porcine pepsin usually contains 2500–3500 units/mg at pH 1, concentrations of pepsin used to reproduce physiological conditions should be 1 mg/ml (1 per cent) or less[4].

Five or six cats were randomly assigned to each study group as shown in *Table 1*. An additional control group of six cats was included to ascertain whether intraoesophageal infusion of saline might affect the oesophageal epithelium. All animals were allowed food and drink *ad libitum* after recovery from anaesthesia at the end of the procedure. Analgesia in the form of Buprenorphine 0·2–0·4 mg/kg was administered subcutaneously to all animals, including controls. All the cats were killed 24 h after the infusion using intravenous sodium pentobarbital 100 mg/kg and the oesophagus was removed intact along with the proximal portion of the stomach. Each specimen was opened

Paper accepted 29 September 1997

longitudinally, pinned to a cork board, and fixed overnight in 10 per cent buffered formalin. The entire distal 5 cm of the oesophagus was processed routinely for histological examination, with longitudinal sections stained with haematoxylin and eosin and evaluated by a pathologist unaware of the treatment sequences.

Each oesophagus was examined and scored by an expanded modification of the scoring system described previously[10]. Briefly, the specimens were scored for basal cell hyperplasia (BCH), intraepithelial leucocytes (IELs), subepithelial leucocytes (SELs) and the presence or absence of ulcers. BCH was defined as the ratio of basal cell layer thickness to total mucosal thickness. Measurements of the thickness of the basal cell layer and total mucosa were performed with an ocular micrometer and BCH was scored as follows: 0, less than 15 per cent; 1 +, 15–40 per cent; 2 +, more than 40 per cent. IELs were scored as number per high-power field (HPF): 0, none; 1 +, 1–2 per HPF; 2 +, more than 2 per HPF. SELs were scored as: 0, none; 1 +, 1–4 per HPF; 2 +, 5 or more per HPF. The distribution or linear extent for BCH, IELs and SELs was assayed as: 0, no abnormality or abnormalities present in a single microscopic focus; 1, one to four foci; 2, more than four foci or diffuse changes. Such microscopic foci had to be distanced physically from similarly affected foci. Thus a combined (degree plus extent) score of 0–4 was possible for each of these parameters. An ulcer was defined as a full-thickness area of epithelial destruction; if none was present, then the ulcer score was 0. When a solitary ulcer was present, the score was 2. When two or more physically discrete ulcers were present in the examined segment, a score of 4 was given. For all specimens, scoring was performed on the most severely affected foci. However, IELs, SELs and BCH were not evaluated within three HPFs of an ulcer. The scores for BCH, IELs, SELs and ulcers were added, so that each cat obtained a total oesophagitis score of 0–16. This scoring system was developed as the result of consideration of histological changes seen in human reflux oesophagitis and in preliminary studies in the cat[9,11].

Statistical analysis

Differences between mean total histology scores were analysed using one-way analysis of variance. If the *F* ratio indicated a significant difference, the Newmann Keuls *post hoc* test was used to identify individual differences between groups. Statistical significance was set at the 0·05 level.

Results

The mean cumulative histology scores following various infusions of acid with and without pepsin are shown in *Table 1*. In the group of animals that received hydrochloric acid alone at a concentration of either 0·1 mol/l (pH 1) or 0·01 mol/l (pH 2), all but one had extensive injury and hence a maximum score of 16. Although these specimens demonstrated extensive ulceration (grade 4), the number and size of ulcers varied from animal to animal. Addition of pepsin at pH 1 or 2 caused a more variable response in the oesophagus, with total scores ranging from 8 to 16 (mean 13·3) and from 7 to 14 (mean 11·7) respectively. Differences between total histology scores at pH 1 and 2 with or without pepsin were not statistically significant. Following infusion of hydrochloric acid 0·001 mol/l (pH 3), there was a sharp reduction in injury to the oesophageal mucosa when compared with lower pHs (*Fig. 1*). There was no evidence of any mucosal injury in the saline control animals (*Fig. 2*).

Table 1 Histology scores following various infusions of acid with and without pepsin

Groups	pH	No. of animals	Mean(s.e.m.) score
Control		6	0
HCl 0·1 mol/l	1	5	15·0(1·0)
HCl 0·1 mol/l + pepsin	1	6	13·3(1·4)
HCl 0·01 mol/l	2	6	15·3(0·7)
HCl 0·01 mol/l + pepsin	2	6	11·7(1·1)
HCl 0·001 mol/l	3	6	1·8(1·6)*
HCl 0·001 mol/l + pepsin	3	6	3·7(1·9)*
HCl 0·0001 mol/l	4	6	0·5(0·2)†
HCl 0·0001 mol/l + pepsin	4	6	0·7(0·3)†

**P* values compared by ANOVA between groups. HCl, hydrochloric acid. **P* = 0·01, †*P* < 0·05 (pH 3 and 4 *versus* pH 1 and 2, analysis of variance)

Detailed results after exposure to a specific concentration of acid are described below.

With pH 1, all cats except one had extensive ulceration, both macroscopic and histological, and therefore had a maximum cumulative score of 16. Some 24 h after a 30-min acid exposure, the number and size of ulcers varied from animal to animal. The mean score in this group was 15 (range 11–16) (*Fig. 3*).

For pH 1 plus pepsin, addition of pepsin in the hydrochloric acid 0·1 mol/l infusion produced a slightly more variable response in the animals, with histological scores varying from 8 to 16 (mean 13·3). Three of six cats in this group had extensive ulceration and inflammation, with a cumulative score of 16.

At pH 2, the mucosa was severely damaged (leading to ulcers) in five of six animals following the acid infusion,

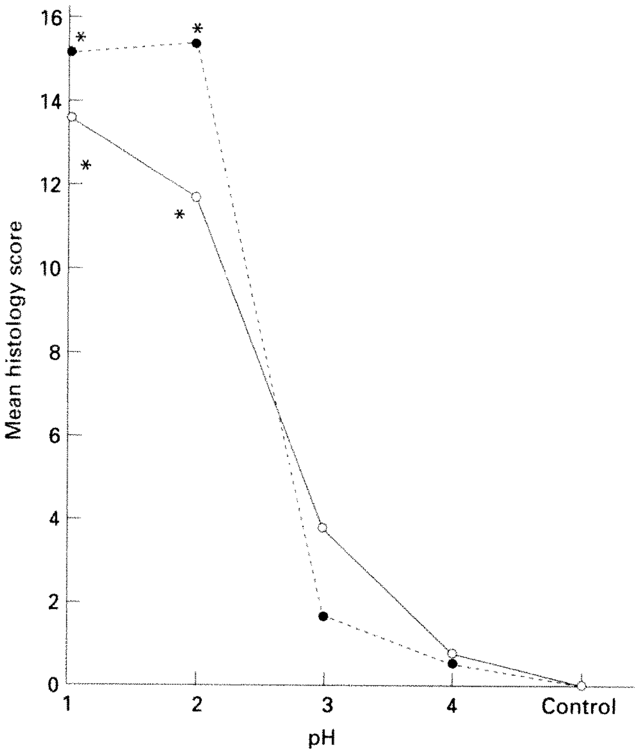

Fig. 1 Histology score at different pH values with (●) or without (○) pepsin. A sharp decline in oesophageal mucosal injury is seen at pH 3, compared with that at pH 1 and 2, with almost no injury at pH 4. Peptic activity appears to be more pronounced at pH 3 than at pH 2. **P* < 0·05 *versus* pH 3 and 4 (analysis of variance)

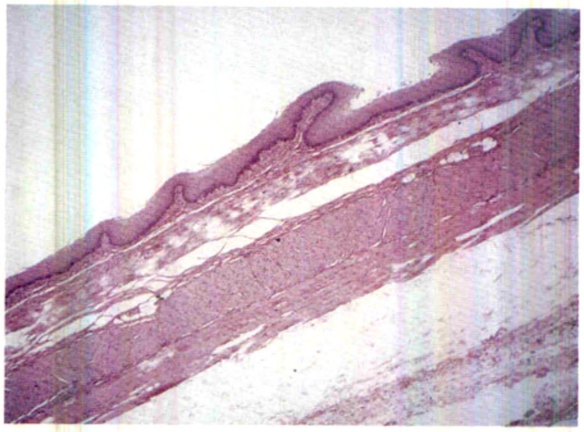

Fig. 2 Saline control cat. Note intact squamous epithelium with thin basal cell layer occupying less than 15 per cent of the mucosal thickness, and unremarkable submucosa and muscularis propria. There is complete lack of inflammation and no layer of keratin. This specimen attained a score of 0. (Haematoxylin and eosin stain; original magnification ×20)

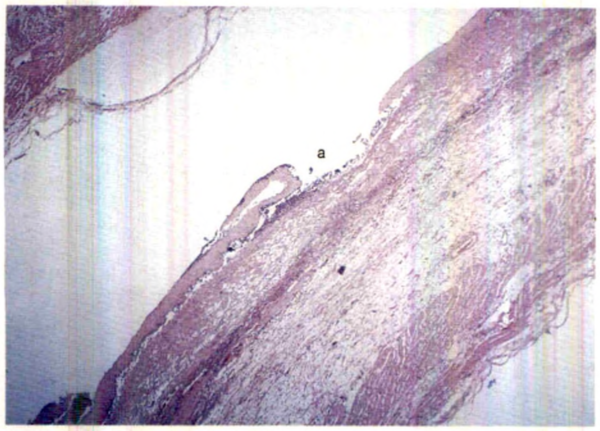

Fig. 3 Microscopic lesions from one study cat. Note the ulcer (a) with prominent mural damage, sloughing of the necrotic mucosa, transmural inflammation and prominent oedema in all the layers typically seen after a 30-min infusion of acid at pH 1 and 2. This specimen attained a maximum score of 16. (Haematoxylin and eosin stain; original magnification ×20)

each attaining a maximum score of 16. The animal in this group without ulcer had a score of 12.

With pH 2 plus pepsin, mucosal injury was much more variable after infusion of hydrochloric acid 0·01 mol/l containing 1 per cent pepsin and the animals had a mean score of 11·7 (range 7–14).

At pH 3, minimal histological changes (early BCH) were identified following infusion of hydrochloric acid 0·001 mol/l. The mean histological score was 1·8 (range 0–10). At autopsy, no gross macroscopic changes were seen in the distal oesophagus in any animal.

With pH 3 plus pepsin, injury was more evident when pepsin was added to hydrochloric acid 0·001 mol/l, with a mean score of 3·7 (range 0–11) (*Fig. 4*).

For pH 4 with or without pepsin, there was no gross or microscopic evidence of injury to the oesophagus in any animal except one, after infusion of hydrochloric acid 0·0001 mol/l with or without pepsin. One cat in each group (with and without pepsin) showed minimal SELs and IELs such that each attained a score of 3 and 4 respectively.

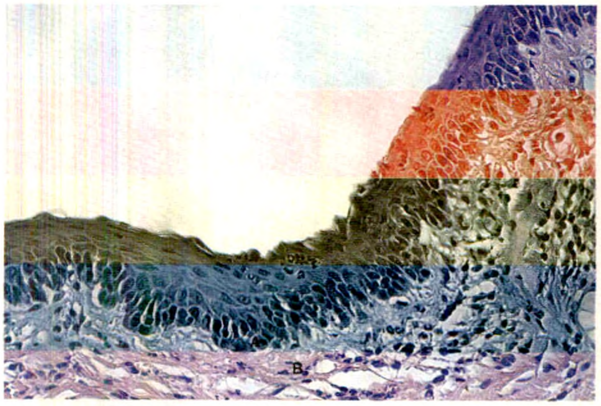

Fig. 4 Oesophageal mucosa after infusion of acid at pH 3 with pepsin. Note the intraepithelial leucocytes (A), subepithelial leucocytes (B) and basal cell hyperplasia (C). This specimen attained a score of 8. (Haematoxylin and eosin stain; original magnification ×40)

Discussion

The oesophageal mucosa is exposed repeatedly to potentially damaging substances both by ingestion and by reflux of noxious gastric contents. These may contain hydrochloric acid as well as pepsin, bile and pancreatic enzymes. *In vivo* studies have shown that each component of the refluxate may induce oesophageal mucosal injury to a greater or lesser degree[5–7]. Various studies support the concept of an 'oesophageal mucosal barrier' which exists in the normal state and is relatively impermeable to luminal acid, thus preventing injury[12,13]. Lillemoe *et al.*[4] showed that disruption of this barrier cannot be equated with pathological injury and that different components of the gastroduodenal contents may have different sites or mechanisms of injury. The development of oesophagitis depends on the duration, frequency, volume and virulence of the refluxed material, the effectiveness of the clearing peristalsis and the resilience of the exposed oesophageal mucosa.

Previous *in vitro* experiments have shown that the optimum pH for pepsin-catalysed reactions is between 1·5 and 2·5[8,14,15]. One experimental study confirmed that the most severe injury to feline oesophageal mucosa occurred between pH 1 and pH 2 as a result of protein denaturation secondary to 'oesophageal burn' caused by the high acid concentration. The addition of pepsin at such a low pH did not increase the severity of injury. At pH 2·5 the injury was more pronounced by the addition of pepsin, possibly due to protein digestion caused by the enzymatic activity of pepsin[8]. Another *in vitro* study[16] suggested that serosal acidification was more damaging than mucosal acidification, indicating that the acid entered the paracellular pathway and the hydrogen ions traversed the basolateral membrane more readily than the mucosal membrane. In a semiquantitative study, Redo and colleagues[17] investigated the effects of hydrochloric acid and porcine pepsin solutions on canine oesophagus for periods of 3–8 h. They demonstrated that pepsin solutions of $\text{pH} < 2$ caused more severe oesophagitis than those with pH >2. Perfusion studies using a rabbit model have revealed that oesophageal mucosal injury was minimal when the perfusate contained acid alone but severe when pepsin was added[18]. In a more recent study with rabbits, Zaninotto *et al.*[19] concluded that acid–peptic injury to the oesophagus was maximal between pH 1·5 and 2·5. Although there was enzymatic activity of pepsin at pH 3, the damage to the oesophageal mucosa was greatly reduced compared with injury observed after exposure to pH 2·5. In the present study, severe mucosal injury was observed at pH 1 and 2 with no detectable change following the addition of pepsin. The injury caused by acid alone was so severe that it may have masked the synergistic effect of pepsin. At pH 3, there was a sharp decline in injury which was somewhat augmented by the addition of pepsin, although not to a significant level. There was no mucosal injury observed at pH 4 with or without pepsin.

Although a high concentration of acid alone may cause oesophagitis, animal studies have suggested that the mechanism of acid injury occurs *parri passu* with activation of pepsin[8,18,19]. Most of the above studies were done in a rabbit model which has an oesophageal epithelium covered by a thick keratin layer (not present in humans), making it difficult to evaluate the histological criteria (segmented leucocytes and reactive epithelial hyperplasia). In contrast the present experiments were performed in a feline model which is a well defined experimental model of acute oesophagitis, frequently used in previous work from the authors' laboratory[9,10,20,21]. The structural layers of the feline oesophagus not only resemble those of humans but also the histological abnormalities of the induced oesophagitis mirror those seen in routine pathology (human) specimens. Previous studies have shown that the cat oesophagus provides an ideal, reproducible and semiquantitative system for studying the biology of oesophagitis.

Prolonged oesophageal monitoring has emerged as the 'gold standard' for the detection of gastro-oesophageal reflux, which is defined as any drop in oesophageal pH below 4. The value of pH <4 has been developed on the basis of previous studies[22,23] which evaluated the effect of acid on the distal oesophagus. The present study has demonstrated that there is no morphological injury at pH 4 and suggests that pH thresholds lower than 3 should be investigated (using the current computerized pH data loggers) in the evaluation of GORD. The likelihood of oesophagitis might be better assessed by detecting oesophageal exposure time at pH <3. In summary, injury to the oesophagus is related to the pH of refluxate and is independent of the presence of pepsin. Acid–peptic injury to the oesophagus occurs at a critical threshold of acid burden (pH <3) as opposed to a graded level of injury based on a pH scale.

Background L-*myc* polymorphism has been documented to be a representative genetic trait which is related an individual's susceptibility to several cancers. However, there have been no reports concerning any significant association between susceptibility to gastric cancer and L-*myc* polymorphism.

Methods The distribution of L-*myc* polymorphism in 61 patients with gastric cancer was determined by polymerase chain reaction-based restriction fragment length polymorphism and compared with that of 107 healthy control subjects.

Results There was a significant difference in the distribution of both genotypes ($P = 0·024$) and allele frequencies ($P = 0·026$) between the two groups. The relative risk of gastric cancer for genotypes with the shorter (S) allele was 3·09 compared with the longer (L) allele homozygote. No significant correlation with clinicopathological features of the cancers except for prognosis was found. The patients with SS genotypes had a worse prognosis than those with LL or LS genotypes ($P = 0·029$).

Conclusion L-*myc* polymorphism may be significant in an individual's susceptibility to gastric cancer in Japan, and may be a useful marker for identifying patients at high risk of developing gastric cancer.

In an effort to find a suitable genetic marker that may allow the detection of a predisposition to the initiation or progression of cancer, restriction fragment length polymorphism (RFLP) of the L-*myc* gene has been investigated in various types of cancer[1–15].

The L-*myc* gene is known to have an EcoRI restriction site at nucleotide position 2886 in intron 2; EcoRI digestion produces two types of allele, the longer (L) allele and the shorter (S) allele, with three genotypes (LL, LS and SS). Previous studies have reported that patients showing either the homozygous S-band (S–S) or the heterozygous S- and L-band (L–S) suffered a much higher incidence of metastasis and a poor prognosis for several cancers[1–2,4,6,12,14]. Two studies have tried to relate L-*myc* polymorphism to gastric carcinogenesis, but reported that there was no association between L-*myc* polymorphism and susceptibility to gastric cancer[5,12]. There was a correlation between susceptibility to metastasis and L-*myc* genotypes containing the S allele[12], but the association of L-*myc* polymorphism with susceptibility to cancer and prognosis remains unsettled.

Recent progress in molecular biological techniques has brought new tools to clinicians[16–20]. A simple and rapid genotyping method using polymerase chain reaction (PCR)-based RFLP has recently been developed which permits discrimination of the three genotypes according to the combination of their alleles. In the present study, this method was used to analyse the distribution of L-*myc* polymorphism both in patients with gastric cancer and in a large group of healthy Japanese individuals in an attempt to resolve the debate as to whether any relationship exists between polymorphism and the risk of developing this neoplasm.

Paper accepted 18 August 1997

Patients and methods

Subjects

These studies were performed in 61 randomly selected patients with gastric cancer resected in 1994 and 1995, and in 107 healthy control volunteers matched for age, sex and ethnic origin with the patient group, and with no history of inbreeding and specific exposure to carcinogens. The volunteers had no symptoms and had been diagnosed to be healthy by regular medical examination such as haematological examination, chest radiography, ultrasonography and gastrofibrescopy. Informed consent was obtained from all participants.

*Determination of the L-*myc* genotype*

Genomic DNA was extracted from normal gastric mucosa of the patients with gastric cancer and from the peripheral blood of healthy volunteers. Approximately 100 ng DNA from each sample was amplified by the PCR. The PCR solution included a 10× PCR buffer (Tris hydrochloride, pH 8·3, 100 mmol/l, potassium chloride 500 mmol/l, magnesium chloride 15 mmol/l, 1 per cent Triton X-100), 2′-deoxyribonucleoside 5′-triphosphate 2·5 mmol/l (a mixture of 2′-deoxyadenosine 5′-triphosphate, 2′-deoxycytidine 5′-triphosphate, 2′-deoxyguanosine 5′-triphosphate and 2′-deoxythymidine 5′-triphosphate, each 10 mmol/l), 1·0 µmol/l of each L-*myc* primer and 1 unit Taq DNA polymerase (Promega, Madison, Wisconsin, USA). The upstream and downstream oligonucleotide primers used for amplification were 5′-ACGGCTGGTGGAGTGGTAGA-3′ and 5′-AAGCTTGAGCCCCTTTGTCA-3′ respectively, which were specifically synthesized to amplify part of intron 2. The conditions for the PCR were: 30 cycles for denaturation at 94°C for 1 min, annealing at 54°C for 2 min and extension at 72°C for 2 min. The PCR product exhibited a 613-base pair fragment. The amplified DNAs were all digested with 5 units EcoRI at 37°C for 1 h. The digested DNA fragments were separated by gel electrophoresis on 2 per cent agarose, and the responsible L-*myc* RFLP alleles were identified in each sample. The genotypes were classified into three types according to the combination of L-*myc* alleles as follows: a homozygote of L alleles which had no EcoRI restriction site, a homozygote of S alleles which had an EcoRI restriction site, and a heterozygote of L and S alleles.

Statistical analysis

The significance of variations in the L-*myc* genotypes and allele frequencies between the patients and control subjects was determined using the χ^2 test for all subjects. Furthermore, another analysis was performed after subdividing the patients with gastric cancer according to clinicopathological factors using the χ^2 test. $P < 0\cdot05$ was considered to be significant in all analyses.

Results

The pattern of EcoRI digestion for L-*myc* fragments (alleles) is shown; there were three genotypes (*Fig. 1*).

The distribution of L-*myc* genotypes found in the patients with gastric cancer and normal controls is given in *Table 1*. The distribution of each genotype in the two populations closely fits the Hardy–Weinberg equilibrium. There was a statistically significant difference in the distribution of the genotypes between the patients and control subjects ($\chi^2 = 7\cdot44$, 2 d.f., $P = 0\cdot024$), and thus there was a significant increase in the frequency of genotypes composed of the S allele in the gastric cancer population compared with the frequency in the normal population ($\chi^2 = 6\cdot25$, 1 d.f., $P = 0\cdot012$) (*Table 2*). The relative risk (odds ratio) of gastric cancer for those with the LS plus SS genotypes compared with the LL genotype was 3·09 (95 per cent confidence interval 1·33–7·21) (*Table 2*).

No significant difference was found when the patients with gastric cancer were subdivided according to clinicopathological factors such as histology, depth of invasion, lymphatic permeation, vascular permeation, lymph node metastasis and clinical stage (*Table 3*). Eighteen (30 per cent) of 61 patients and 33 (30·8 per cent) of 107 volunteers were smokers. There was no association between smoker or non-smoker status and L-*myc* allele distribution. Seven of 46 patients with LL or LS genotypes died from recurrent disease, while seven of 15 patients with an SS genotype died from recurrent disease. There was a significant difference between L-*myc* alleles and prognosis ($P = 0\cdot029$).

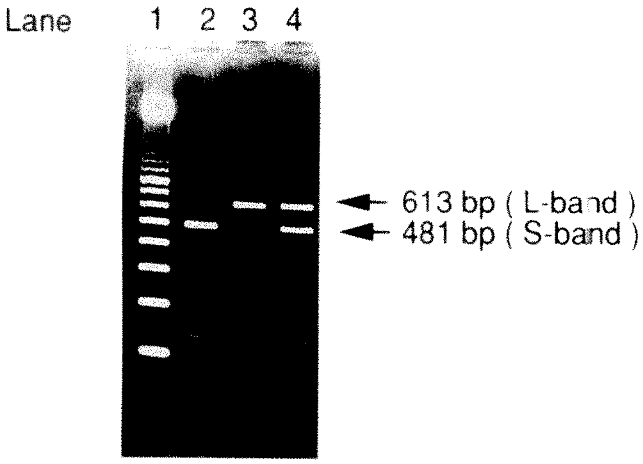

Fig. 1 Digestion pattern of L-*myc*. Amplified DNA fragments were digested with EcoRI, then applied to a 2 per cent agarose gel containing ethidium bromide. Lane 1, 100-base pair (bp) ladder used as a molecular marker; lane 2, DNA from the homozygote for the shorter (S) allele (481 bp), showing complete digestion with EcoRI; lane 3, DNA from the homozygote for the longer (L) allele (613 bp), lacking the EcoRI site; and lane 4, DNA from the heterozygote for the S and L allele. The other digested fragment of S allele (132 bp) was seen as a ghost band (lanes 2 and 4)

Table 1 Distribution of L-*myc* restriction fragment length polymorphism genotypes in patients with gastric cancer and healthy subjects

		No. with genotype		
	n	SS	LS	LL
Patients	61	15 (25)	38 (62)	8 (13)
Controls	107	18 (16·8)	55 (51·4)	34 (31·8)

Values in parentheses are percentages. L-*myc* genotypes have shorter (S) and/or longer (L) alleles. $P = 0\cdot024$ (2d.f., χ^2 test)

Table 2 Distribution of L-*myc* restriction fragment length polymorphism genotypes in patients with gastric cancer and healthy subjects

		No. with genotype	
	n	SS + LS	LL
Patients	61	53 (87)	8 (13)
Controls	107	73 (68·2)	34 (31·8)

Values in parentheses are percentages. L-*myc* genotypes have shorter (S) and/or longer (L) alleles. There was a significant difference in the distribution of genotypes (SS plus LS *versus* LL) between patients and controls ($P = 0\cdot012$, 1 d.f., χ^2 test). The relative risk of gastric cancer for genotypes with the S allele (SS plus LS) compared with the LL genotype was 3·09 (95 per cent confidence interval 1·33–7·21)

Table 3 Distribution of L-*myc* genotypes in patients with gastric cancer subdivided according to clinocopathological factors

Variable	No. of subjects*	L-*myc* genotype LL	LS	SS	*P*
Histology					
Differentiated	28	4	15	9	0·51
Undifferentiated	22	3	15	4	
Depth of invasion					
No serosal invasion	32	3	22	7	0·65
With serosal invasion	26	4	15	7	
Lymphatic permeation					
Positive	20	3	13	4	0·80
Negative	38	4	24	10	
Vascular permeation					
Positive	41	4	26	11	0·59
Negative	17	3	11	3	
Lymph node metastasis					
Positive	24	4	16	4	0·42
Negative	34	3	21	10	
Clinical stage					
I and II	36	4	23	9	0·86
III and IV	20	3	13	4	

L-*myc* genotypes have shorter (S) and/or longer (L) alleles. *Patients showing indistinct data in each category were excluded

The frequency of the S allele was greater than that of the L allele in the patient group (0·56 *versus* 0·44), in contrast to 0·43 *versus* 0·57 in the normal control group ($\chi^2 = 4{\cdot}93$, $P = 0{\cdot}026$). The relative risk of gastric cancer for those with the S allele compared with the L allele was 1·70 (95 per cent confidence interval 1·23–4·13).

Discussion

The L-*myc* gene was isolated initially on the basis of its high level of amplification in a subset of human small-cell lung cancers, and it is thought to be a nuclear oncogene activated late in tumorigenesis[21,22]. Since a study of L-*myc* RFLP in Japanese patients with lung cancer was first reported in 1988[1], many investigators have analysed the L-*myc* RFLP types in patients with lung cancer[4,7,9,15] and other malignant tumours, such as renal cancer[2], gastric cancer[5,12], bone or soft tissue sarcomas[11], oral cancer[6], colorectal cancer[3,10], breast cancer[12] and hepatocellular carcinoma[8]. It remains controversial as to whether L-*myc* polymorphism may affect susceptibility to tumour. Although Kato *et al.*[11] reported an association between SS genotype and susceptibility to bone and soft tissue sarcoma in male patients, no such association was found with the incidences of lymphoma and leukaemia[13] and breast cancer[14]. In contrast, Taylor *et al.*[8] showed a protective effect of the SS genotype in hepatocellular carcinoma.

There was a significant difference in the distribution of L-*myc* RFLPs between patients with gastric cancer and healthy Japanese subjects in the present study. This positive finding persisted when the patients were classified into two genotypes, 'LS plus SS' and 'LL' types, or when they were analysed according to allele frequency. Therefore, it is concluded that, at least for Japanese patients, the polymorphism of L-*myc*, especially in individuals having the S allele, may play a significant role in the genetic susceptibility to gastric cancer. These findings are incompatible with two previous studies of gastric cancer[5,12]. The distribution of genotypes or allele frequency in the present control population was statistically similar to that in Australians[13], Indians[6], Norwegians[9] and white Caucasians[5,7], and to that reported in the Japanese population[11], but not to that reported by Ishizaki *et al.*[12]. Several reports on lung cancer are also inconsistent[7,9]. A possible explanation for these contradictory results may be that they are due to differences in environmental factors or in the ethnic origins of the population analysed. The cancer incidence of many tumour types, if not all, will also vary because of both environmental and genetic factors. Further studies on the allele distribution in relation to ethnic differences are required to clarify the genetic susceptibility to cancer, such as in black Americans who show a higher frequency of the SS genotype of L-*myc*[7].

The reason why polymorphism of the L-*myc* gene is related to genetic susceptibility to gastric cancer is unknown. It is possible that a gene or genes that are closely associated with L-*myc* on the same chromosome are related. Interestingly, it was observed recently that the L-*myc* genotype was associated with a significantly higher level of allele loss from chromosomal arms[10]. Consequently it may be that L-*myc* polymorphism might not influence biological behaviour of a tumour except as a marker in linkage disequilibrium with an as yet unknown susceptibility gene. On the other hand, it is of course possible that the L-*myc* oncogene itself is directly involved.

Although the L-*myc* genotype has consistently been analysed using Southern blotting in previous studies, this study utilized a molecular genotyping method involving PCR–RFLP. As the epidemiological risk factors for gastric cancer involve individual acquired conditions such as smoking, alcohol intake and gastritis[23], this method should be applicable to individuals at high risk in an attempt to select such individuals more objectively. Testing several genetic polymorphisms simultaneously has the potential to identify individuals with an extremely high risk of developing cancer. This has profound implications for prevention since such high-risk individuals may be screened intensively as well as potentially treated with several preventive approaches. From a clinical viewpoint, this method appears to be an accurate and reliable approach for the mass screening of a large number of patients, because it can be performed rapidly and simply by examining only a small amount of genomic DNA isolated from peripheral blood or a buccal smear. L-*myc* RFLP analysis may therefore be a useful marker for predicting a higher risk for gastric cancer, at least in the Japanese population.

Some studies have suggested that the presence of the S allele was associated with a poor prognosis because of metastasis. Since a close correlation between the S allele and an individual's predisposition to metastasis, especially to lymph nodes and distal organs, was reported in lung cancer[1], similar associations have been shown in renal[2], cancer[6], gastric[12] and breast[14] cancer. The present study disclosed similar results, that patients with the S–S alleles showed a worse prognosis than those with L–L or L–S types. In contrast, no correlation between L-*myc* RFLP and metastasis has been reported in colorectal[3], breast[12] or lung[7,9] cancer.

Surgical Research Society Abstracts

The following abstracts were presented at the 87th meeting of the Surgical Research Society. The meeting was organized by the Academic Department of Surgery, United Medical and Dental School, Guy's and St Thomas', and held on 8–9 January 1988 at Guy's and St Thomas' Hospital, London, UK. Ninety-seven papers were presented during the scientific sessions. The Patey Prize was awarded to Dr R. L. Loveday for her paper entitled 'Genetic analysis of breast tumours by comparative genomic hybridization'.

Monocyte chemotactic protein 1 accelerates thrombus resolution

C. L. McGuinness, J. Humphries, A. Smith and K. G. Burnand, *Department of Surgery, St Thomas' Hospital, London, UK*

Background Monocyte infiltration into venous thrombi increases with time and this is associated with raised plasminogen activator levels. Monocyte chemotactic protein 1 (MCP-1) is chemotactic for monocytes. It was hypothesized that administration of MCP-1 might increase monocyte recruitment by the thrombus and enhance its resolution.

Methods Home Office approval was obtained for a rat model of thrombosis to be used in two experiments. (1) Two cohorts of five animals received 1 μg recombinant rat MCP-1 or its carrier. Specimens were harvested at 1 week and paraffin sections were stained with Martius Scarlet Blue and a rat monocyte marker (clone ED-1). Slides were scored blindly by three independent observers for macrophage, erythrocyte, collagen, fibrin and smooth muscle cell content, lumen size and degree of recanalization. (2) Thrombi from control and test cohorts were weighed at 7 and 10 days ($n = 22$).

Results (1) Organization scores were found to be significantly higher in the MCP-1 group (control median 29, test median 59; $P < 0{\cdot}0005$). There was no significant interobserver difference in scores. (2) Thrombus weights in the MCP-treated group were significantly greater than those in the control group ($P = 0{\cdot}02$). Thrombus weights in the control group were higher at 10 than 7 days whereas in the MCP group, thrombus weights were lower at 10 days than at 7 days.

Conclusion (1) Infusion of MCP-1 accelerates thrombus maturity. (2) It is known from models of thrombosis that after induction, thrombus increases in weight for a number of days before resolving. It is possible that the thrombus weight–time curve may have been shifted to the left by MCP-1 administration. Early organization may be beneficial in resolving human thrombi making MCP-1 of potential therapeutic use.

Calcium antagonists accelerate elastin destruction in a model of aneurysmal disease

J. R. Boyle, I. M. Loftus, S. Goodall, M. Crowther, P. R. Bell and M. M. Thompson, *Department of Surgery, Leicester University, Leicester, UK*

Background Abdominal aortic aneurysms (AAAs) are characterized by changes in the extracellular matrix of the arterial media, in particular a reduction in elastin concentration. These changes are mediated by increased levels of endogenous matrix metalloproteinases (MMPs). MMP activity is influenced by a number of therapeutic agents and recently calcium channel blockers have been shown to increase the proteolytic activity of MMP-2 secreted by vascular smooth muscle cells. It may therefore be hypothesized that calcium antagonists may potentiate the activity of MMPs in aneurysmal disease and thus accelerate AAA expansion. In this study, the ability of amlodipine to influence elastin degradation, was assessed in a previously described model of aneurysmal disease.

Methods Porcine aortic segments ($n = 8$) were preincubated in exogenous pancreatic elastase for 24 h before culture in standard conditions for 6 days with amlodipine 10 and 100 $\mu g\,l^{-1}$. Control segments were cultured both without amlodipine and without elastase. At the termination of culture MMPs were extracted from the tissue and quantified by a combination of substrate gel enzymography and immunoblotting. The volume fractions of elastin and collagen were determined by stereological analysis of elastic Van Gieson-stained sections.

Results Gel enzymography demonstrated significantly increased MMP-9 activity in the amlodipine-treated segments and this raised activity was reflected in a significant destruction of medial elastin.

Aorta	Elastin (%)	MMP-9 (units)
Cultured control	54·2 (45·4–62·2)	2·86 (2·55–3·17)
Elastase	40·5 (27·2–48·8)	2·81 (2·60–3·71)
Elastase/amlodipine 10 $\mu g\,l^{-1}$	33·6 (27·9–40·8)	4·22 (3·98–4·86)†
Elastase/amlodipine 100 $\mu g\,l^{-1}$	27·0 (18·5–38·2)*	4·18 (3·93–5·07)‡

Values in parentheses are interquartile ranges. $^*P < 0{\cdot}05$, $^†P < 0{\cdot}01$, $^‡P < 0{\cdot}02$

Conclusion Therapeutic ranges of amlodipine significantly enhanced elastin degradation and potentiated MMP-9 activity within the aortic organ cultures. These data suggest that amlodipine may accelerate AAA growth.

Oral eicosapentaenoic acid reduces experimental human pancreatic tumour growth in mice with severe combined immunodeficiency

M. D. Barber, K. C. H. Fearon and J. A. Ross, *University Department of Surgery, Royal Infirmary of Edinburgh, Edinburgh, UK*

Background The authors have recently shown that eicosapentaenoic acid (EPA), a fatty acid derived from fish oil, will attenuate cachexia in patients with advanced pancreatic cancer. Others have suggested that EPA will slow experimental tumour growth in mice but most have used mixed fish oil preparations or administered the agent by non-physiological routes. This study aimed to assess the effect of dietary high-purity EPA upon the growth of a human pancreatic cancer cell line in immunocompromised mice.

Methods Fragments of tumour derived from the MIAPaCa-2 human pancreatic cancer cell line were transplanted subcutaneously in 5–6-week-old female mice with severe combined immunodeficiency after Home Office approval. From the day after tumour implantation mice were fed a purified fat-free diet to which was added oil to make up 5 per cent of the final diet weight, using either corn oil or 95 per cent pure EPA as free acid (4 per cent, plus 1 per cent corn oil). Mice were killed before the tumour burden became excessive at around 3 weeks.

Results Mice fed the diet enriched with EPA had significantly smaller tumours than control animals (median 2810 *versus* 4960 mm^3; $P = 0{\cdot}023$, Mann–Whitney U test). Liver and spleen were the main site of metastases and these organs were significantly lighter in EPA-fed animals than those fed corn oil

($P<0\cdot001$) suggesting a reduced metastatic burden. Mice fed EPA ate significantly less food than controls (2·25 *versus* 3·05 g day^{-1}, $P=0\cdot021$). As diet restriction has been suggested to inhibit carcinogenesis the experiment was repeated but matched amounts of food were supplied. Again tumours were significantly smaller (3080 *versus* 4800 mm^3, $P=0\cdot027$) and liver and spleens were significantly lighter ($P<0\cdot02$) with EPA.

Conclusion It is concluded that EPA 6–8 g kg^{-1} within the diet will slow experimental tumour growth and metastatic spread in mice.

Claudication grade: effect on total antioxidant capacity and systemic vascular permeability

E. P. L. Turton, I. Spark, K. G. Mercer, D. C. Berridge, R. C. Kester and D. J. A. Scott, *Department of Vascular Surgery, St James's University Hospital, Leeds, UK*

Background The leucocyte has been implicated as a mediator of ongoing vascular damage in patients with peripheral vascular disease (PVD). The chronic consequences of PVD may therefore be reflected by systemic changes in total antioxidant capacity and vascular permeability commensurate with increasing severity of PVD. The aim of the study was to assess if increasing grade of PVD, according to Society for Vascular Surgery/International Society for Cardiovascular Surgery classification influences total antioxidant defences and systemic vascular permeability.

Methods Data were collected from 25 patients with grade 2 claudication (ankle to brachial pressure index (ABPI) 0·1(0–0·2)), 28 patients with grade 1 claudication (ABPI 0·8(0·6–0·8)), and 22 patients with grade 0 claudication (controls) (ABPI 1·2(1·1–1·3)). Patient demographics were matched. Total antioxidant capacity (TAC), urine albumin to creatinine ratio (UACR) and neutrophil CD11b expression were determined from resting samples collected in the morning.

Results There was no significant difference in TAC between the three groups. Grade 2 claudicants had significantly higher urine albumin leak ($P<0\cdot01$), and CD11b expression ($P<0\cdot01$), compared with the control group and grade 1 claudicants.

Category of PVD	No.	TAC	Neutrophil CD11b (m.c.f.)	UACR (mg mmol^{-1})
Grade 0	22	720 (630–858)	2·5 (2·2–3·2)	0·5 (0–1·3)
Grade 1	28	813 (636–909)	3·1 (2·4–3·9)*	2·0 (0·9–3)*
Grade 2	25	765 (400–980)	11·5 (7·3–15·2)†	6·4 (1–7·5)†

Values are median (i.q.r.). m.c.f., mean channel fluorescence. *$P<0\cdot05$, †$P<0\cdot01$ *versus* control group (Mann–Whitney *U* test)

Conclusion This study, for the first time provides evidence of the systemic changes associated with increasing severity of PVD. Although there is an increase in resting neutrophil activation and endothelial damage with increasing severity of PVD this is not balanced by changes in total antioxidant defences.

Long-term renal transplant function is predicted by interstitial staining for collagen III in 6-month protocol biopsies

S. Williams, E. Bailey, K. P. G. Harris*, P. N. Furness† and M. L. Nicholson, *Departments of Surgery, *Nephrology and †Pathology, Leicester General Hospital, Leicester, UK*

Background Chronic transplant rejection has emerged as the commonest cause of long-term renal allograft failure. Early identification of those grafts at risk could allow targeting of specific therapies aimed at delaying this process.

Methods A consecutive series of 48 renal transplant recipients with 5-year follow-up data were studied. All patients underwent protocol needle-core transplant biopsies at 1, 3 and 6 months after operation. All patients were immunosuppressed with cyclosporin and prednisolone (with or without azathioprine). In this study the 6-month protocol biopsies were analysed by computerized histomorphometry. No patient had clinical rejection at the time of the biopsy. Immunostaining for collagen III, tenascin and infiltrating leucocytes was performed using an indirect immunoperoxidase technique. Interstitial area stained (%) was measured by a blinded research associate using a semi-automatic image analysis system. Images from biopsy sections were transferred in digital form by a microscope-mounted video camera to a microcomputer fitted with a frame grabber card. The area fraction occupied by the substance under study was computed using the program NIH Image on non-counterstained sections. The results were related to glomerular filtration rates measured at 6, 12 and 24 months after transplant using rank correlation coefficients.

Results Six-month glomerular filtration rate correlated with percentage area of collagen III ($r=0\cdot42$, $P=0\cdot005$), tenascin ($r=-0\cdot41$, $P=0\cdot007$) and leucocytes ($r=-0\cdot36$, $P=0\cdot02$). Furthermore, a percentage area of collagen III of more than 40 per cent at 6 months was associated with a significantly lower GFR at 24 months than a percentage area of 40 per cent or less (mean(s.d.) 30·8(3·6) *versus* 44·8(3·6) ml per min per 1·73 m^2, $P=0\cdot01$). Donor age correlated with collagen III and tenascin staining at 6 months ($r=0\cdot33$, $P=0\cdot03$) but not with leucocyte staining, and was also predictive of long-term graft outcome.

Conclusion Grafts with poor long-term function can be predicted using early (6 month) protocol biopsies immunostained for collagen III, tenascin and leucocytes. The predictive graft changes at this time may reflect donor characteristics rather than those arising *de novo* in the recipient.

Local or general anaesthesia for carotid endarterectomy: a formal trial is overdue

T. A. J. Calvey, A. J. McCleary, A. Bodenham, S. Homer-Vanniasinkam, A. I. D. Mavor and M. J. Gough, *Departments of Vascular Surgery and Anaesthetics, The General Infirmary at Leeds, Leeds, UK*

Background Although carotid endarterectomy (CEA) performed under local anaesthesia (LA) allows optimum cerebral monitoring and maintains cerebral autoregulation it is suggested that hypertension and catecholamine release increase cardiac morbidity. However a recent meta-analysis of non-randomized studies (2070 LA, 3447 general anaesthesia (GA)) suggests that death (0·8 *versus* 1·2 per cent), stroke (2·0 *versus* 5·3 per cent) and myocardial infarction (MI) (0·6 *versus* 1·3 per cent) are less frequent in patients who have LA.

Methods In a prospective study 89 CEAs were performed under LA (superficial and deep cervical plexus block; 20 ml 0·5 per cent bupivacaine, 20 ml 1 per cent prilocaine) and 101 under GA (1 mg alfentanil, 0·5–2·0 per cent isoflurane, nitrous oxide/oxygen). Although non-randomized, patients had a free choice as to the type of anaesthetic. The sex ratio (LA M:F 65:24, GA 57:44), mean age (67·9 *versus* 68·1 years) and history of ischaemic heart disease (31 *versus* 34 per cent), hypertension (66 *versus* 56 per cent), smoking (52 *versus* 64 per cent) and diabetes (11 *versus* 14 per cent), confirmed that the two groups were similar as did the indications for surgery (LA *versus* GA): transient ischaemic attack (38 *versus* 38 per cent), cerebrovascular accident (CVA) (33 *versus* 32 per cent), amaurosis (23 *versus* 25 per cent), asymptomatic (6 *versus* 5 per cent) and the presence of greater than 70 per cent bilateral stenoses (37 *versus* 35 per cent).

Results The outcome of CEA is shown in the *Table*.

	LA	GA
n	89	101
Shunted	15 (17)	67 (66·3)
Stump pressure < 50 mmHg	46 (52)	67 (66·3)
30-day stroke rate	0	4 (4·0)
Perioperative MI	1 (1)	3 (3·0)
Death	1 (1)	2 (2·0)

Values in parentheses are percentages. $P = 0{\cdot}057$ (30-day CVA rate); $P = 0{\cdot}046$ (combined MI/CVA)

Conclusion These results support the concept that all complications of CEA may be less frequent when surgery is performed under LA and reinforce the need for a prospective randomized trial.

Polymorphisms within the tumour necrosis factor region affect survival of patients with oesophageal cancer

L. O'Mahony, J. Jackson*, C. Feighery*, K. Mealy† and T. P. J. Hennessy, *Departments of Surgery and *Immunology, St James's Hospital, Dublin, Ireland and †Western General Hospital, Edinburgh, UK*

Background Genetically, the control of tumour necrosis factor (TNF) α production has been associated with a number of polymorphic sites present near the TNF locus in the class III region of the major histocompatibility complex (MHC). This study examines the TNFB locus, which has previously been shown to influence the TNF-α production both *in vitro* and *in vivo* in patients with oesophageal cancer and investigates if correlations exist between cytokine production and clinical outcome.
Methods Genomic DNA was isolated from the peripheral blood of 46 patients with cancer and 47 controls. Using polymerase chain reaction, a 782 base-pair fragment containing the TNFB locus was amplified and subjected to NcoI restriction analysis to detect which TNFB allele was present.
Results Both the cancer and control groups had similar TNFB allelic frequencies. In the cancer group, 6 per cent were homozygous for TNFB1 (associated with low TNF-α production), 57 per cent were heterozygotes (TNFB1, 2) and 37 per cent homozygous for TNFB2 (associated with high TNF-α production). Significant correlations were made between survival and TNFB status, with 0, 49 and 82 per cent of patients with TNFB1, 1 ($n = 3$), TNFB1, 2 ($n = 26$) and TNFB2, 2 ($n = 17$) alleles respectively surviving their first year ($P < 0{\cdot}004$).
Conclusion While there is overproduction of TNF-α in patients with oesophageal cancer, this seems to be inversely associated with the allele TNFB1 which underexpresses TNF-α. This implies that some other polymorphic site may be associated with increased TNF-α production in these patients. TNFB status is prognostic in predicting poor patient survival and this may be due to linkage with other loci within the TNF or MHC regions. These studies indicate that genetic predisposition may direct the inflammatory response in cancer patients and may have prognostic significance.

K-*ras* mutation and 8p12 deletions both occur frequently in early colorectal tumours

N. Khan, S. Chughtai, N. Cruickshank and D. Morton, *University Department of Surgery, Queen Elizabeth Hospital, Birmingham, UK*

Background Mutational analysis of colorectal cancers suggests that different genetic changes can produce tumours with distinct clinicopathological features. Chromosome 8p has been implicated in deletional studies. K-*ras* mutations occur with higher frequency in early tumours. K-*ras* activation has been studied in combination with deletions at 8p12.
Methods Eleven adenomas and 70 consecutive colorectal cancers including seven $T_1 N_0 M_0$ tumours, were genotyped from tumour extracted DNA. K-*ras* mutations were examined by the amplification refractory mutation scheme test; interstitial deletions on 8p12 were identified using polymorphic microsatellite markers (DS8-87, -505, -513, -259, -278).
Results Seven adenomas had K-*ras* mutations, three of which also had allelic loss at 8p12. Four of seven T_1 tumours had isolated 8p12 deletions compared with two of 63 advanced tumours ($P = 0{\cdot}0005$). K-*ras* mutations were seen in four of seven T_1 tumours and 15 of 63 advanced tumours ($P = 0{\cdot}08$). Both mutations occurred in three of four T_1 carcinomas. This relationship was not seen in the advanced tumours ($P = 0{\cdot}02$). Absence of both changes was found in only one T_1 lesion and in 47 advanced tumours ($P = 0{\cdot}02$).
Conclusion These findings show a clear predilection of these two changes for early tumours, and these events tend to occur in the same tumours. This suggests multiple genetic pathways for colorectal cancer, and may indicate that certain pathways will result in neoplasms with a less aggressive phenotype.

Serum vascular endothelial growth factor in breast cancer

K. Heer, H. Kumar, P. J. Drew, J. N. Fox, P. J. Carleton, J. R. T. Monson and M. J. Kerin, *The University of Hull, Academic Surgical Unit, Castle Hill Hospital, Cottingham, UK*

Background Vascular endothelial growth factor (VEGF) is one of the most potent angiogenic cytokines. Its intratumoral levels correlate with microvessel density, nodal metastasis and disease-free survival. This study evaluates the relation between serum VEGF and various pathological indices of breast cancer.
Methods Serum VEGF 165 was assayed before operation in 135 patients with breast malignancies and compared with serum VEGF levels in 72 healthy female controls. All tumours were staged by a single pathologist according to the tumour node metastasis classification.
Results Serum VEGF was raised in all stages of breast cancer. Levels in nodal, recurrent and metastatic disease were significantly higher than those in controls. Patients with ductal carcinoma *in situ* (DCIS) had raised levels compared with controls. Some 67 per cent of patients had raised VEGF levels compared with 11 per cent with raised CA15-3 and 13 per cent with abnormal carcinoembryonic antigen levels.

	VEGF (pg ml^{-1})	P*
Controls ($n = 72$)	173·8 (92·5–252·5)	
DCIS ($n = 8$)	450·4 (301·8–795·2)	0·002
Ductal carcinoma ($n = 95$)	307·7 (155·5–483·0)	< 0·0005
Lobular carcinoma ($n = 16$)	207·1 (118·7–379·8)	0·32
ER positive ($n = 62$)	305·9 (179·7–485·2)	< 0·0005
ER negative ($n = 20$)	267·8 (94·2–523·7)	0·1

Values are median (interquartile range). ER, oestrogen receptor. *Mann–Whitney *U* test

VEGF levels were not significantly raised in patients with lobular cancer or those with ER-negative tumours.
Conclusion Serum VEGF shows a correlation not only with tumour stage and cancer cell type but also with ER status. This may have implications in the study of hormones in the aetiology, pathogenesis and prognosis of breast cancer. As serum VEGF is more sensitive than currently employed tumour markers, it may have a role in monitoring disease prognosis in patients with breast cancer.

Positron emission tomography in assessing axillary lymph node status in breast cancer

I. Smith, K. N. Ogston, F. W. Smith*, P. F. Sharp*, A. K. Ah-See, S. D. Heys, J. A. Jibril and O. Eremin, *Departments of Surgery and *Bio-medical Physics and Nuclear Medicine, University of Aberdeen, Aberdeen, UK*

Background The single most important prognostic factor in breast cancer is axillary node involvement by tumour. Assessment of nodal status requires axillary dissection resulting in additional time in hospital and postoperative morbidity. A reliable non-invasive method of determining axillary node status would be valuable. Positron emission tomography (PET) produces images based on the distribution and metabolism of administered positron-emitting compounds, reflecting functional rather than anatomical characteristics of the imaged tissue. PET, therefore, may allow identification of metastatic tumour in regional lymph nodes. The role of PET was assessed in staging the axilla in breast cancer.
Methods Patients with untreated breast cancer underwent PET, using between 105 and 185 Mbq 2-deoxy-2-(F18) fluoro-D-glucose, of the axillae and upper thorax before surgery. Patients were examined clinically following PET. The accuracy of clinical and PET node staging was compared with node histology following surgical excision.
Results Some 50 patients underwent PET imaging. Twenty-one had involved axillary nodes at histology; PET demonstrated 19 involved nodes. Twenty-nine patients did not have any nodes involved at histology; PET showed involvement in one and none in 28. Therefore, PET had a specificity of 97 per cent and a sensitivity of 90 per cent (accuracy 94 per cent). Clinical examination had a specificity of 90 per cent and a sensitivity of 57 per cent .
Conclusion PET has a high sensitivity and specificity for detecting axillary node involvement in breast cancer. Its use in staging of breast cancer may obviate the need for axillary surgery in many patients.

Antioestrogen therapy does not affect cell death or cell proliferation in comedo ductal carcinoma *in situ* of the breast

A. Gandhi, P. A. Holland, W. F. Knox*, C. S. Potten† and N. J. Bundred, *Departments of Surgery, *Pathology and †Epithelial Biology, University of Manchester, Manchester, UK*

Background Over 50 per cent of screen-detected ductal carcinoma *in situ* (DCIS) lesions are of the comedo subtype which are usually oestrogen independent. The value of antioestrogen therapy in preventing recurrence of DCIS following breast conserving surgery is currently under evaluation.
Methods Using an *in vivo* model for human DCIS the effect of antioestrogen treatment on programmed cell death (apoptosis) and cellular proliferation (Ki67 immunoreactivity) in DCIS lesions was examined. In each experiment, athymic nude mice (median no. 16 (range 12–20)) were implanted with eight DCIS xenografts per mouse and given either no treatment or weekly injection of 0·1 ml Faslodex (a pure antioestrogen) for 2 weeks. Xenografts were then removed and apoptotic and Ki67 indices compared between treatment groups by examining cell morphology on sections stained with haematoxylin and eosin (no. of cells exhibiting apoptosis/total no. of cells counted) or by immunohistochemistry (Ki67 proliferation index).
Results All non-comedo lesions and three of 15 comedo DCIS lesions were oestrogen receptor (ER) positive. Pretreatment apoptotic and proliferative rates were significantly higher in comedo than non-comedo lesions ($P < 0·0001$ and $P = 0·02$ respectively, Mann–Whitney U test).

	Comedo DCIS ($n = 15$)		Non-comedo DCIS ($n = 5$)	
	Apoptotic index (%)	Ki67 index (%)	Apoptotic index (%)	Ki67 index (%)
Pretreatment	1·6 (0·7–3·7)	16·2 (7–46)	0·4 (0·1–0·6)	2·2 (0–16)
Control group	1·4 (0–3·5)	16·9 (2–29)	0·4 (0·1–1·7)	7·0 (2–21)
Antioestrogen group	0·8 (0·4–3·6)	14·8 (14–18)	1·0 (0·5–2·0)	8·1 (4–11)
P*	n.s.	n.s.	0·04	n.s.

Values are median (range). n.s., Not significant. *Mann–Whitney U test

Following antioestrogen treatment, non-comedo DCIS (usually ER positive) displayed increased apoptotic cell death compared with controls whereas comedo DCIS (usually ER negative) was unresponsive.
Conclusion Women with comedo DCIS are unlikely to benefit from antioestrogen therapy and other therapeutic strategies need to be investigated.

Accuracy of one-stop diagnosis for 1110 patients presenting to a symptomatic breast clinic

A. ElTahir, J. A. Jibril, J. Squair*, S. D. Heys, A. K. Ah-See, G. Needham†, H. Deans†, F. Gilbert†, M. McKean‡, L. Smart‡ and O. Eremin, *Professorial Surgical Unit and Departments of *Public Health, †Radiology and ‡Cytology, University of Aberdeen and Aberdeen Royal Hospitals NHS Trust, Aberdeen, UK*

Background To minimize delay and anxiety and reduce unnecessary open biopsies, triple assessment with immediate reporting has been used in this symptomatic breast clinic since 1991. The effectiveness and reliability of the process requires careful evaluation. The aim of this study was to establish the accuracy of the diagnostic modalities used and the efficacy of this one-stop diagnostic policy.
Methods The data on 1110 patients, newly presenting to the symptomatic breast clinic between January and July 1993, were analysed and the subsequent 3-year follow-up and outcome established. Sensitivity, specificity and predictive values were determined using standard statistical analysis (SPSS for Windows).
Results Fine-needle aspiration cytology (FNAC) provided the highest (97·3 per cent) overall prediction of benign and malignant lesions, with a sensitivity of 93·5 per cent and specificity of 98·1 per cent. Ultrasonography provided 97·0 per cent overall prediction with a sensitivity of 88·9 per cent and specificity of 97·4 per cent. Mammography provided 96·4 overall prediction with a sensitivity of 93·2 per cent and a specificity of 96·7 per cent. When the mammogram or ultrasonographic scan were reported benign, the false-negative rate was 0 per cent. The false-positive and false-negative rates for FNAC were 2·4 and 1·4 per cent respectively. Following assessment, a diagnosis was made in 96 per cent of patients; 62 per cent were discharged at the first clinic visit.
Conclusion The one-stop symptomatic breast clinic provides a quick, accurate and effective means of establishing a diagnosis.

Desmoglein 2 expression in primary breast cancer and its relation to a series of prognostic markers

E. L. Davies, J. M. W. Gee*, R. A. Cochrane, R. I. Nicholson*, A. K. Sharma, W. G. Jiang and R. E. Mansel, *Department of Surgery and *Tenovus Cancer Centre, University Hospital of Wales, Cardiff, UK*

Background Desmoglein 2 (Dsg2) is a novel calcium-dependent transmembranous glycoprotein forming a subfamily of the cadherin group of adhesion molecules. Its role as a potential metastatic suppressor molecule has been demonstrated in transitional and squamous cell carcinomas and in the authors' recent *in vitro* data. However its expression and role in breast cancer *in vivo* has yet to be established.

Methods The aim of this study was to demonstrate and establish the level of immunohistochemical (IHC) expression of Dsg2 in breast cancer specimens ($n = 68$) as well as in ductal carcinoma *in situ* (DCIS) ($n = 3$), tumour-associated normal (TAN) ($n = 11$) and normal ($n = 9$) breast tissue. Second, the IHC level of Dsg2 expression and a series of prognostic markers (oestrogen and progesterone receptors, Ki67, epidermal growth factor receptor, grade and size of tumour, lymph node involvement and menopausal status) were compared.

Results The majority of cancers (98 per cent) demonstrated membranous staining for Dsg2. However, Dsg2 expression was significantly reduced in breast cancer when compared with normal and TAN breast tissue ($P < 0{\cdot}0001$) but not with DCIS ($P = 0{\cdot}67$). A significant inverse relationship between tumour size and Dsg2 expression was demonstrated ($P = 0{\cdot}012$), but no correlation could be shown between Dsg2 level and the other prognostic markers.

Conclusion These data suggest that Dsg2 may have a potential role in local breast cancer progression, but have not provided evidence for a metastatic suppressor role for Dsg2.

Effect of antioestrogens on BRCA-1 mutated breast tissue compared with normal breast

M. D. Bramley, R. B. Clarke†, A. Howell*, E. Anderson† and A. D. Baildam, *Departments of Surgery and *Medical Oncology, University Hospital of South Manchester and †Department of Clinical Research, Christie Hospital, Manchester, UK*

Background Women found to have the BRCA-1 genotype are randomized into tamoxifen *versus* placebo breast cancer prevention trials, but little is known of tamoxifen's effects on their breast tissue.

Methods The effects of tamoxifen and a pure antioestrogen (ICI 182780) were studied on breast tissue from women with known BRCA-1 mutations ($n = 3$), other 'high risk' women in whom genetic testing was not possible ($n = 10$) and normal women undergoing benign breast biopsies ($n = 6$). Tissue was implanted into the flanks of athymic nude mice ($n = 20$) and 2 weeks later treated either with slow-release oestradiol (E_2 2 mg; $n = 12$) or control pellets ($n = 8$). One week later control mice were treated with vehicle ($n = 4$), tamoxifen (1 mg day^{-1}; $n = 2$), or ICI 182780 (5 mg week^{-1}; $n = 2$) injections for 2 weeks and E_2 mice with vehicle ($n = 4$), tamoxifen (1 mg day^{-1}; $n = 4$), or ICI 182780 (5 mg week^{-1}; $n = 4$). Implants were removed for histological examination and assessment of proliferation (Ki67) using immunocytochemistry at weeks 2, 3, 4 and 5. This work has ethics committee and Home Office approval.

Results Of 1370 implants retrieved, 1008 (73·6 per cent) contained normal breast nodules. In all groups there was a significant rise in Ki67 expression after E_2. In the normal risk group, tamoxifen could reduce Ki67 to near control levels (mean(s.d.) 1·9 (1·5) *versus* 1·9 (1·9) per cent cells positive). In the 'high risk' group, tamoxifen had no significant effect on Ki67 but after ICI 182780, Ki67 fell from 3·5 (3·4) in the E_2 alone group to 1·8 (2·6) ($P = 0{\cdot}009$, Mann–Whitney U test). In the BRCA-1-mutated group Ki67 fell from 4·5 (6·3) in the E_2 alone group to 2·2 (4) after tamoxifen and 2·1 (2·7) after ICI 182780.

Conclusion The BRCA-1-mutated breast proliferates in response to oestrogen. This proliferation is abrogated by tamoxifen and ICI 182780 but the latter appears more potent.

Possible therapeutic role of short chain fatty acids in diversion colitis of the neobladder

L. Solomon, A. Jennings, P. Malone, J. Primrose and A. Cooper, *Departments of Urology and Surgery, Southampton University Hospitals NHS Trust, Southampton, UK*

Background Short chain fatty acids (SCFAs), butyrate especially, are a major energy substrate for colonic mucosal cells. They are also antiproliferative differentiation inducers. Diversion colitis may be reversed by their instillation. A similar condition (and subsequent neoplasia) can occur in neobladders reconstructed using colon. Proposals to treat this with intravesical SCFAs have led to an investigation of their effects on urothelium.

Methods Wistar rats were given 0·4 ml of an SCFA cocktail (butyrate 40 mmol l^{-1}) intravesically daily for 5 days. A [14C] butyrate tracer was also used. Bladder histology was performed up to 14 days thereafter. Primary normal urothelial cells were isolated from ureter by sequential ethylenediamine tetra-acetic acid and collagenase IV treatment, and grown on for not more than five passages in a supplemented keratinocyte serum-free medium. A tetrazolium cytotoxicity assay was performed on cells seeded in 96-well plates, exposed to SFCA or control for 2–72 h, washed and grown on for 5 days.

Results Instillation of SCFAs caused no histological change. Butyrate was readily absorbed and 89 per cent of absorbed counts were sequestered in the liver 1 h after instillation. The *in vitro* reduction of biomass directly related to drug concentration and exposure time, e.g. 40 per cent ($P < 0{\cdot}01$) at 2 h and butyrate 20 mmol l^{-1}; 10 mmol l^{-1} had no effect.

Conclusion The cytostatic effect of SCFAs seen *in vitro* is not reflected in gross histology. However, there is substantial absorption through urothelium. The prospects for therapeutic use are promising.

Effect of sympathetic co-transmitters on human mesenteric arteries and veins

D. J. Birch, P. Karoon*, P. B. Boulos and G. Burnstock*, *Departments of Surgery and *Anatomy, University College London Medical School, London, UK*

Background Sympathetic perivascular nerves contain noradrenaline (NA), neuropeptide Y (NPY) and adenosine 5′-triphosphate (ATP) as co-transmitters. The effect of these transmitters on human mesenteric arteries and veins was investigated.

Methods Mesenteric vessels from patients with non-inflammatory conditions were dissected from operative specimens. Organ-bath pharmacology on ring segments was used to determine the cumulative dose–response curves for NA alone and with a subthreshold dose of NPY, NPY alone and ATP.

Results

Transmitter	Vessel	n	E_{max} (%)	EC_{50}
NA	artery	6	125·3 (9·8)†	5·23 (0·06)‡
	vein	11	64·1 (9·7)	6·07 (0·04)
NPY	artery	6	0	0
	vein	6	Variable contraction at doses $> 3 \times 10^{-8}$ mol l^{-1}	
NA + NPY 3×10^{-8} mol l^{-1}	artery	6	110·6 (2·2)	5·29 (0·02)
	vein	6	100·8 (17·8)¶	6·47 (0·04)**
ATP	artery	7	—	3·22 (0·07)*§
	vein	8	—	4·31 (0·28)*

Values are mean(s.d.). E_{max}, maximal contraction to exogenous transmitter as percentage of contraction to potassium chloride 120 mmol l^{-1}; EC_{50}, $-$log of dose giving 50 per cent maxima contraction; *p[A]$_{25}$ (dose giving 25 per cent maximal contraction to KCl 120 mmol l^{-1}). †$P < 0{\cdot}001$, ‡$P < 0{\cdot}0001$, §$P < 0{\cdot}005$ *versus* veins (two-sample t test); ¶$P < 0{\cdot}02$, **$P < 0{\cdot}001$ *versus* NA only (paired t test)

Conclusion These data suggest that both NA and ATP are involved in sympathetic neurotransmission in human mesenteric vessels. NPY in mesenteric veins modulates the effect of NA but its role in mesenteric arterial sympathetic nerves is unclear. Studies on other vessels demonstrated a greater effect of NPY on arteries than veins, highlighting wide variations in vascular control between vascular beds. This study forms the basis for further investigation into the control of mesenteric blood flow in health and disease.

Mucosal regeneration and malignant change in inflammatory bowel disease

H. R. H. Patel, A. Hewer, D. H. Phillips and F. C. Campbell, *Department of Surgery, University of Newcastle, Newcastle-upon-Tyne, UK*

Background Inflammatory bowel disease has a 14·8-fold increased cancer risk, by obscure mechanisms. This study tests the hypothesis that regenerating intestinal epithelium has increased sensitivity to DNA damage from luminal mutagens and initiation of carcinogenesis.
Methods A novel rodent model of regeneration was used, involving transplantation of crypt stem cell preparations (364 grafts). Metabolic defensive responses including Cytochrome P450 (Cyp), glutathione-S-transferase (GST) and uridine diphosphoglucuronosyl transferase (EGT) isoforms were assessed by Western blot in regenerating *versus* normal intestinal epithelium, after exposure to the mutagen benzo[a]pyrene. DNA damage was assessed quantitatively by ^{32}P-postlabelling for DNA adduct formation.
Results Epithelium at early stages of regeneration lacked metabolic defences (GSTA3, UGT in early regeneration *versus* Cyp2B, GSTA1/2, GSTA4, GSTP1, UGT in control) and sustained high levels of DNA adducts. DNA damage declined and metabolic defences recovered in late stage regeneration (e.g. mean(s.d.) 24 (17) adducts per 10^8 nucleotides in early regeneration *versus* 12 (9) adducts per 10^8 nucleotides in late regeneration ($P < 0·03$)).
Conclusion Intestinal epithelial regeneration provides a window of susceptibility to DNA damage which may initiate carcinogenesis.

Efficacy of laparoscopic ultrasonography in detecting liver metastases during colorectal cancer surgery

H. Kumar, J. E. Hartley, K. Heer, G. S. Duthie, G. R. Avery* and J. R. T. Monson, *University of Hull, Academic Surgical Unit and *Department of Radiology, Castle Hill Hospital, Cottingham, UK*

Background The search for liver metastases before surgery forms an accepted part of colorectal cancer surgical practice. Intraoperative ultrasonography with manual palpation of the liver is the gold standard for screening for liver metastases. The purpose of this study was to demonstrate the efficacy of laparoscopic ultrasonography in detecting liver metastases at operation in comparison to conventional modalities.
Methods A prospective controlled study was undertaken. Some 73 consecutive patients undergoing laparoscopic colorectal resection for malignancy were recruited. Patients underwent preoperative liver ultrasonography and peroperative blinded laparoscopic ultrasonography using a flexible-tipped 6·5 MHz curved array transducer, capable of scanning the liver to a depth of about 10 cm.
Results Conventional ultrasonography was negative in all 73 patients. All patients have had Magnetic Resonance Imaging (MRI) scans at appropriate intervals except two who died at operation and two who could not tolerate MRI. Metastases were identified during initial peroperative laparoscopic inspection in one case and no additional lesions were found on laparoscopic ultrasonography in this patient. On nine other occasions the laparoscopic scan was abnormal. There were no false-negative laparoscopic ultrasonography examinations. The presence of metastases was confirmed in two patients diagnosed to have metastases on laparoscopic ultrasonography. Of the seven abnormal laparoscopic ultrasonography scans, three patients with suspicious lesions on laparoscopic ultrasonography were found to have metastases on MRI; in one it was deemed to be a cyst. Three remaining patients with suspicious lesions on laparoscopic ultrasonography were confirmed on serial MRI scans, to have benign lesions. Follow-up of all patients (median (interquartile range) 27·5 (18–38) months) has revealed liver metastases in three further patients at 12, 13 and 18 months. All three had normal MRI scans at the time of surgery.
Conclusion This study supports a role for laparoscopic ultrasonography in the detection of liver metastases and in the selection of patients for further sophisticated imaging. Laparoscopic ultrasonography is cheaper and better than conventional ultrasonography and is as sensitive as MRI.

Smooth muscle cell proliferation and *in vivo* implantation using gamma interferon-stimulated SV40 large T antigen is feasible

B. N. Shah, T. Partridge* and T. G. Allen-Mersh, *Departments of Surgery and *Muscle Cell Biology (MRC Clinical Sciences Centre), Imperial College School of Medicine, London, UK*

Background Anal continence is frequently impaired by an internal sphincter deficit. Previous attempts to produce an anal 'neosphincter' using smooth muscle cell culture have been complicated by difficulties in cell proliferation and identification. The authors have previously demonstrated smooth muscle proliferation in cell culture using a system that drives cell proliferation in H2k mice. This is a transgenic mouse which has a DNA construct, consisting of a thermolabile mutant of the SV40 virus large T gene driven by a promoter integrated into its genome. Gamma interferon is activated by this promoter causing expression of large T driving cells into proliferation at 33°C. The mdx mouse does not possess the gene for dystrophin, so transplanted cells can be identified using antibodies against dystrophin in conjunction with smooth muscle markers. The authors have now assessed whether these *in vitro* proliferated smooth muscle cells are viable after subsequent *in vivo* implantation.
Methods Single cells isolated from the oesophagogastric junction were cultured using substrate attached explants derived from H2k transgenic mice. These cells were cloned and expanded *in vitro* by cell culture. They were then fixed and identified by immunocytochemistry for the expression of antigens consistent with smooth muscle. These smooth muscle clones were then pelleted into a fibrin clot and inserted either into the subcapsular kidney region or the denatured tibialis anterior muscle of mdx/nude host mice.
Results Implanted smooth muscle cells characterized by antibody staining could be identified under the renal capsule beyond 5 weeks and in the tibialis anterior beyond 3 months following implantation. However, some smooth muscle clones became transformed *in vivo* and subsequently formed tumours.
Conclusion Smooth muscle proliferation in cell culture and *in vivo* implantation is feasible, but the problem of neoplastic transformation has not been overcome.

Immunohistological modulation after nutritional supplementation with omega-3 essential fatty acids in patients with inflammatory bowel disease

Y. Z. Almallah, S. W. B. Ewen*, N. A. G. Mowat†, P. W. Brunt, T. S. Sinclair†, S. D. Heys and O. Eremin, *Departments of Surgery and *Pathology, University of Aberdeen and †Gastro-intestinal Unit, Aberdeen Royal Infirmary, Aberdeen, UK*

Background Patients with ulcerative colitis (UC) appear to have altered reactivity of gut-associated lymphoid tissue, with intense infiltration of the mucosa with immunocompetent cells. The authors have shown previously that dietary supplementation with the omega-3 essential fatty acids (EFAs) results in significant systemic immunosuppression. The aim of this study, therefore, was to evaluate the *in situ* effect of EFAs on distal UC.

Methods Patients received fish oil extract (eicosapentaenoic acid 3·2 g, docosahexaenoic acid 2·4 g) ($n=9$) or placebo ($n=9$) daily, in a double-blind manner for 6 months. Monthly assessment included (1) disease activity using clinical, sigmoidoscopic and histological scores and (2) immunohistochemical analysis (immunoglobulins, CD profiles) of rectal biopsies, using monoclonal antibodies and quantitative video analysis.

Results In the EFA group, there was improvement in disease activity and histological scores (median (range) 8 (3–10) and 5 (4–9) respectively) compared with pretreatment evaluation (16 (7–25) and 9 (7–10)) ($P<0·05$, Wilcoxon pairs test). Before supplementation, patients with distal UC ($n=18$) showed significantly higher numbers of immunoglobulin (Ig) G- and IgM-containing cells and cells expressing CD3 (T cells), CD20 (B cells) and human leucocyte antigen HLA DR, compared with healthy controls ($n=8$). After 6 months of supplementation, the two groups of patients showed the following results:

	EFA group ($n=9$)	Placebo ($n=9$)	P*
IgM (%)	25·7 (15·0 to 74·9)	34·1 (21·0 to 53·8)	0·04
CD3†	− 154 (− 173 to − 120)	− 32 (− 86 to 40)	0·01
CD20†	− 52 (− 82 to − 6)	− 5 (− 10 to 16)	0·04

Values are median (range). †Change from baseline. *Mann–Whitney *U* test

Conclusion This study has demonstrated suppression of *in situ* immune reactivity in patients with distal UC receiving EFA supplementation. This has important implications for therapy in patients with UC.

Ruptured abdominal aortic aneurysm is associated with raised levels of soluble tumour necrosis factor receptors

D. J. Adam, W. P. Stuart, J. A. Ross, C. V. Ruckley and A. W. Bradbury, *Vascular Surgery Unit, University Department of Surgery, Royal Infirmary, Edinburgh, UK*

Background Soluble tumour necrosis factor receptors (sTNF-Rs) are considered to be endogenous TNF antagonists. In sepsis, raised levels are associated with increased mortality rate. sTNF-Rs in haemorrhagic shock and early ischaemia–reperfusion injury have not been studied. Serum sTNF-R levels were examined in patients with ruptured abdominal aortic aneurysm (AAA).

Methods Sixteen patients undergoing repair of ruptured AAA and ten undergoing elective repair of intact AAA were studied. Type I and II sTNF-Rs were measured by enzyme-linked immunosorbent assay before operation (point 1), and immediately before (point 2), and 5 min (point 3) and 6 h (point 4) after aortic clamp release.

Results Type I sTNF-Rs were only significantly higher in patients with rupture at point 3 (median (range) 1·1 (0·2–3·5) *versus* 0·5 (0·2–1·1) ng ml^{-1}; $P<0·05$, Mann–Whitney *U* test). Data for type II sTNF-R are shown below.

Sample point	Ruptured AAA	Intact AAA	P*
1	4·0 (2·0–14·7)	2·1 (2·0–6·3)	< 0·05
2	3·3 (2·0–9·1)	2·1 (2·0–2·2)	< 0·001
3	3·2 (2·0–9·7)	2·1 (2·0–2·2)	< 0·001
4	10·0 (2·1–18·5)	2·5 (2·0–5·9)	< 0·001

Values are median (range). *Mann–Whitney *U* test

At point 4, type II sTNF-Rs were significantly higher in five patients with rupture who died (14·6 (9·7–18·0) ng ml^{-1}) than in 11 who survived (4·8 (2·1–18·5) ng ml^{-1}) ($P<0·05$).

Conclusion Ruptured AAA is associated with increased sTNF-R expression. Raised levels of type II sTNF-R are associated with increased postoperative mortality rate.

Both ETA and ETB receptors mediate proliferation in isolated human saphenous vein smooth muscle cells

D. H. Olojugba, K. E. Porter, P. R. F. Bell and N. J. M. London, *Department of Surgery, University of Leicester, Leicester, UK*

Background Smooth muscle cell proliferation is central to the development of intimal hyperplasia. Endothelin has mitogenic effects and is implicated in the aetiology of intimal hyperplasia. However, there is tissue, species and functional variation in cell endothelin receptor expression. As a result it is not clear which receptors mediate smooth muscle cell proliferation in human saphenous vein grafts. The aim of this study was to determine which receptors promote endothelin-induced smooth muscle cell proliferation in human saphenous vein.

Methods Smooth muscle cells explanted from human long saphenous vein were used at second passage. These cells were seeded into multiwell plates at a concentration of 1×10^4 per ml and growth arrested for 72 h in 0·4 per cent fetal calf serum (FCS). They were then incubated in minimal growth promoting media (2·5 per cent FCS) to which was added endothelin 10 nmol^{-1} with or without an endothelin receptor antagonist. These were the mixed ETA/ETB antagonist Bosentan (10 μmol^{-1}), the ETA antagonist BQ123 (3 μmol^{-1}), and the ETB receptor antagonist BQ788 (3 μmol^{-1}). A similar series of cells cultured in 2·5 per cent and 15 per cent FCS acted as negative and positive controls respectively. Cell counts were performed in duplicate every second day and the drugs and media were replaced in the remaining wells. Each experiment lasted for 12 days and was repeated in cells from eight different patients.

Results Cell proliferation was expressed as a ratio of the amount of growth of each group to the amount of growth in the 2·5 per cent FCS control. Endothelin produced a median (range) growth ratio of 1·5 (0·9–1·9). Bosentan produced a median (range) growth ratio of 0·9 (0·6–1·5). That of BQ788 and BQ123 was 0·9 (0·7–1·3) and 1·0 (0·8–1·3) respectively. All the antagonists significantly reduced endothelin-induced smooth muscle cell proliferation ($P=0·02$, Wilcoxon test) but there was no significant difference between each antagonist.

Conclusion Endothelin-induced proliferation of smooth muscle cells isolated from human saphenous vein can be mediated via both ETA and ETB receptors.

Hyperhomocysteinaemia is associated with abdominal aortic aneurysm

S. Caldwell, S. C. Martin*, A. C. Hilton*, W. A. Bartlett*, A. F. Jones and D. A. Mosquera, *Departments of Surgery and *Clinical Chemistry, Birmingham Heartlands Hospital, Birmingham, UK*

Background Hyperhomocysteinaemia is a recognized risk factor for premature peripheral vascular disease. No previous study has examined an association with abdominal aortic aneurysms (AAA), despite anecdotal reports of aneurysms in patients with homocystinuria. The aim of this case-controlled study was to determine the prevalence of hyperhomocysteinaemia in patients with AAA.

Methods Plasma was separated and frozen within 1 h of venepuncture from fasting subjects and controls. Homocysteine (HCY) was measured in a high-pressure liquid chromatography assay with electrochemical detection. Control results were logarithmically transformed to give a reference range (mean ± two standard deviations) of 8·86–14·25 $\mu\text{mol l}^{-1}$.

Results Results are as follows:

	AAA ($n = 14$)	Controls ($n = 30$)
HCY (μmol l^{-1})	17·5 (12·90–18·50)*	11·30 (9·37–14·07)

Values are median (interquartile range). *$P = 0\cdot0109$ *versus* controls (Mann–Whitney *U* test)

Hyperhomocysteinaemia (HCY greater than 14·25 μmol l^{-1}) was present in 11 of 14 patients with AAA, but only seven of 30 controls ($\chi^2 = 8\cdot349$, $P = 0\cdot001$).
Conclusion This is the first report of an association between hyperhomocysteinaemia and AAA. More patients are required for confirmation, but these findings raise the possibility of managing small aneurysms, and patients at risk with vitamin supplements.

Increased expression of the endothelial specific Tie-1 receptor by hypoxia

M. J. McCarthy, D. Hughes, M. Crowther, N. Brindle and P. R. F. Bell, *Department of Surgery, University of Leicester, Leicester, UK*

Background Tissue ischaemia is a common and important problem, especially in the lower limb. A novel treatment currently showing promise in clinical trials is to revascularize the limb by stimulating new blood vessel growth with angiogenic growth factors, notably vascular endothelial growth factor (VEGF). A major limitation of this approach is that VEGF only activates initial stages of vessel growth and produces immature vessels prone to thrombosis and leakage. Maturation to patent vessels requires activation of another set of receptors, those for Tie. Tie-1 and Tie-2 are endothelial cell-specific tyrosine kinase receptors. However, nothing is known about the factors which control the level of Tie-1 or its ligands in the ischaemic or revascularizing limb. The aim of the study was to determine whether expression of Tie-1 or its ligands is modulated in endothelial cells by hypoxia and VEGF, conditions which are encountered in the ischaemic and VEGF revascularizing limb.
Methods Bovine aortic endothelial cells were subjected to hypoxic conditions for varying lengths of time (0–24 h). Tie-1 expression was analysed by Western blotting.
Results Tie-1 expression increased almost fourfold ($P = 0\cdot017$) after 24 h of hypoxia. A similar increase was observed following stimulation with VEGF. Using a technique based on the measurement of Tie-1 ectodomain binding, Tie-1 ligand expression was shown to be insensitive to hypoxia.
Conclusion These data demonstrate, for the first time, that hypoxia and VEGF upregulate the expression of Tie-1 in vascular endothelium. If this occurs *in vivo*, it suggests that existing and newly forming blood vessels in the ischaemic limb are likely to have increased sensitivity to Tie ligands. The ability to activate this system, with either endogenous or exogenous ligand, is likely to lead to vessel maturation and the formation of patent vessels.

Cerebral cytokine production during carotid surgery: markers of a significant ischaemic insult

T. A. J. Calvey, S. P. Cavanagh, S. M. Parkin, S. Estdale, A. I. D. Mavor, S. Homer-Vanniasinkam and M. J. Gough, *Vascular Surgical Unit, The General Infirmary at Leeds, Leeds and Department of Biomedical Sciences, Bradford University, Bradford, UK*

Background The proinflammatory cytokines interleukin (IL) 6 and IL-8 are produced as part of the acute-phase response to ischaemia–reperfusion in skeletal muscle and myocardium and may influence both the local and systemic leucocyte response to the ischaemic insult. It is unknown whether a similar response occurs following temporary occlusion of the carotid vessels during carotid endarterectomy (CEA).
Methods Cerebral cytokine production was assessed in venous samples obtained from the ipsilateral jugular bulb before cross-clamping the carotid vessels (T_0) and at 4 h (T_4) and 24 h (T_{24}) following reperfusion in 18 patients undergoing CEA (nine under general anaesthesia, nine under local anaesthesia). Il-6 and IL-8 levels were compared with systemic levels in 20 controls (minor elective surgery, no ischaemia–reperfusion) measured following induction of general anaesthesia and at the same times after operation.
Results

	IL-6		IL-8	
	Control	CEA	Control	CEA
T_0	2·0(0·4)	10·5(3·7)	6·1(1·1)	0·8(0·4)
T_4	29·9(5·7)	98·2(24·0)	8·8(2·5)	11·6(3·6)
T_{24}	26·0(3·9)	68·3(8·5)	11·7(4·8)	22·1(4·7)

Values are mean(s.d.)

Following CEA there was a significant rise in cerebral IL-6 and IL-8 production compared with precross-clamp levels (T_4 and T_{24}, $P < 0\cdot0001$). These levels were also significantly higher than those in the control patients (T_4 IL-6: $P < 0\cdot0005$; T_{24} IL-6: $P < 0\cdot0001$, IL-8: $P < 0\cdot02$). There was a non-significant trend ($P < 0\cdot2$) to suggest that cytokine production, and therefore the ischaemic injury, was less in patients given local anaesthesia for CEA.
Conclusion These results confirm that CEA results in significant cerebral ischaemia. The effectiveness of potential cerebral protection strategies could be assessed by determining the cytokine response to surgery.

Smoking and shear stress-induced endothelial cell anoikis may be prevented by the amino acid taurine

E. Fennessy, J. H. Wang, C. Kelly and D. Bouchier-Hayes, *Royal College of Surgeons in Ireland, Department of Surgery, Beaumont Hospital, Dublin, Ireland*

Background Vascular endothelial cells (ECs) require attachment to the extracellular matrix (ECM) for growth and survival. Loss of this anchorage by disruption of the ECM results in anoikis, or apoptosis from lack of anchorage. Anoikis may be the result of either mechanical or chemical stresses. Smoking-induced endothelial damage has previously been shown to increase the number of circulating ECs. It is not clear whether such cells are apoptotic or necrotic. Cigarette smoking increases shear stress (SS) and oxidant-mediated EC damage. The authors have previously demonstrated that the amino acid taurine can reverse the abnormal function of ECs in smokers and can prevent oxidant-mediated EC apoptosis *in vitro*. It was hypothesized that (1) increases in SS *in vitro* result in increased EC death by apoptosis and that (2) taurine treatment of young smokers may prevent the increase in apoptosis induced by cigarette smoking.
Methods Seven healthy smokers with a self-reported smoking history of 2 pack-years and 11 control non-smoking subjects were studied. Circulating carcasses of ECs were isolated from peripheral blood samples and counted by the method of Hladovec and Rossman. Cells were stained with fluorescein-labelled antihuman factor VIII monoclonal antibody to confirm the identity of these ECs. Apoptosis of the cells was assessed with the terminal deoxynucleotidyl transferase-mediated 2′-deoxyuridine 5′triphosphate nick end labelling technique. Samples for the estimation of EC desquamation were taken before and after inflation and subsequent deflation of a cuff to 200 mmHg for 2 min ($n = 8$), and before and after treatment of smokers with taurine 1·5 g day^{-1} for 5 days ($n = 7$).

Results

	Baseline	Increase in SS	Non-smokers	Smokers	Smokers + taurine
No. of apoptotic cells per 0·9 μl	1·06(0·29)	2·4(0·77)*	0·93(0·42)	3·29(1·43)†	1·11(0·59)‡

Values are mean(s.d). *$P = 0·002$ *versus* baseline; †$P = 0·02$ *versus* non-smokers; ‡$P = 0·006$ *versus* smokers

Conclusion This study reveals that acute increases in SS and chronic cigarette smoking induce anoikis. The amino acid taurine has the capability to prevent EC apoptosis and may have an important role in EC functioning and survival.

Ruptured abdominal aortic aneurysm is associated with inhibition of systemic fibrinolysis

D. J. Adam, W. P. Stuart, C. A. Ludlam, C. V. Ruckley and A. W. Bradbury, *University Departments of Surgery and Haematology, Royal Infirmary, Edinburgh, UK*

Background It has been suggested that ruptured abdominal aortic aneurysm (AAA) is associated with systemic fibrinolysis and that haemorrhage may be limited by antifibrinolytics such as aprotinin. For the first time, thrombin generation and systemic fibrinolysis in patients undergoing repair of ruptured and intact AAA was examined.
Methods Ten patients undergoing repair of ruptured AAA and nine patients undergoing repair of intact AAA were studied. Tissue plasminogen activator (t-PA) activity, plasminogen activator inhibitor (PAI) activity and prothrombin fragment (PF) 1 + 2 were measured before operation, immediately before and 5 min after aortic clamp release and 24 h after operation.
Results Before operation rupture was associated with significantly increased PAI activity (median (range) 36·5 (20·6–38·8) *versus* 8·2 (3·2–21·7) units ml^{-1} for non-rupture; $P < 0·001$, Mann–Whitney U test) and significantly decreased t-PA activity (median (range) 0·12 (0·06–0·43) *versus* 0·49 (0·14–3·2) units ml^{-1} for non-rupture; $P < 0·01$). In both groups there was a significant increase in PF 1 + 2 above the normal range (0·4–1·1 nmol l^{-1}) but this was significantly greater in patients with rupture (median (range) 9·0 (5·4–11·6) *versus* 2·2 (0·7–7·1) nmol l^{-1}; $P < 0·001$). These changes persisted throughout the course of surgery.
Conclusion Ruptured AAA is associated with systemic thrombin generation and inhibition of systemic fibrinolysis. These data do not support the use of antifibrinolytic therapy in patients operated for ruptured AAA.

Genetic analysis of breast tumours by comparative genomic hybridization

R. L. Loveday, J. Greenman, P. J. Drew, J. R. T. Monson and M. J. Kerin, *Department of Surgery, Academic Surgical Unit, University of Hull, Cottingham Road, Hull, UK*

Background Molecular genetic studies have identified several mutations, chromosomal deletions and amplifications in breast cancer. However most techniques limit analysis to one gene or chromosomal region. This study concentrated on the entire genome using a new technique, comparative genomic hybridization (CGH).
Methods CGH is based on the competitive hybridization of two differentially labelled DNA samples to normal metaphase spreads. Tumour DNA is labelled with a green fluorochrome and normal reference DNA is labelled with a red fluorochrome. Image analysis compares the intensity of the green to red staining and calculates the ratio thus allowing copy number changes to be identified throughout the genome. Fifteen consecutive breast tumours were studied. All were staged according to standard tumour node metastasis classification. Reference DNA was extracted from the patients' lymphocytes and, in order to distinguish between somatic and germline mutations, the tumour specimens were also compared using standard reference DNA (Vysis).
Results Recurrent regions of amplification involved 1q (12 of 15), 3q (nine of 15), 5q (eight of 15), 12p (eight of 15) and 20p (nine of 15). The means(s.d.) number of amplifications per tumour was 12·7(6·4), involving 8·5(3·3) chromosomes in each tumour. Recurrent regions of deletion involved 17p (seven of 15) and 15p (seven of 15). The mean(s.d.) number of deletions per chromosome was 10(4·2), involving 5·1(3·8) chromosomes in each tumour. The greatest number of aberrations (30) was found in a T$_4$ tumour. The sites of most of the copy number changes were distinct from those of currently known cancer genes.
Conclusion These results have implications for future studies and suggest a multistep and multigene involvement in breast carcinogenesis.

Lack of correlation between failure of gut barrier function and sepsis following major surgery

S. Kanwar, A. C. J. Windsor, P. M. Murchan, S. Elhasani, S. Perry, P. J. Guillou and J. V. Reynolds, *Professorial Surgical Unit, St. James's University Hospital, Leeds, UK*

Background Failure of the gut mucosal barrier to exclude bacteria and endotoxin from the portal and systemic circulation is incriminated in the development of sepsis and multiple organ failure. There are compelling animal data to support this thesis, but corroborative clinical evidence is sparse. Patients undergoing major resectional surgery were investigated to determine the relationship of circulating endotoxin to intestinal permeability and outcome of sepsis.
Methods Fifty-six patients undergoing curative resectional surgery for upper gastrointestinal malignancy were monitored for 30-day septic morbidity (intra-abdominal abscesses/empyema and pneumonia). Intestinal permeability, C-reactive protein (CRP) and serum immunoglobulin (Ig) antiendotoxin (EndoCAb) antibodies were determined before operation (PRE) and on postoperative day 1 (POD1).
Results

	Sepsis ($n = 20$)	No sepsis ($n = 36$)	P†
Intestinal permeability*			
PRE	0·06(1·16)	0·06(0·18)	0·66
POD1	0·18(3·83)	0·18(0·87)	0·53
Serum CRP (mg l^{-1})			
PRE	7·7(26·1)	10·5(40·3)	0·81
POD1	125·8(38·7)	117·1(45·2)	0·77
IgM EndoCAb (MU ml^{-1})			
PRE	96(116)	154(139)	0·27
POD1	85(62)	92(75)	0·49

Values are median (s.d.). *Lactose : mannitol ratio. †Mann–Whitney U test

There was no significant difference in intestinal permeability, CRP and endotoxin exposure before operation and on the day after surgery between the two groups. Logistic regression analysis did not identify a significant association between intestinal permeability, CRP and level of endotoxin with septic outcome.
Conclusion Patients who developed sepsis following major upper gastrointestinal surgery did not differ before surgery with respect to intestinal permeability, acute-phase response and endotoxin exposure, compared with patients who did not develop sepsis. Moreover, the magnitude of change in all the parameters on the first postoperative day did not differ in the two groups. There is no support from this study to incriminate the measured changes

in gut barrier function or endotoxin exposure to the development of sepsis.

Dynamic real-time magnetic resonance imaging for occult groin pain

S. Gould, G. Lamb, N. Vaughan, W. Gedroyc, A. Mansfield and A. Darzi, *Academic Surgical Unit, Imperial College of Medicine at St Mary's and Centre for Biological and Medical Systems, Imperial College, London, UK*

Background Persistent groin pain without clinical signs is a difficult diagnostic problem. Some patients have occult inguinal hernias, but others have musculotendinous injuries not necessarily requiring surgery. No existing imaging modality is sufficiently sensitive to reliably distinguish the two. Therefore the negative surgical exploration rate is high. Interventional magnetic resonance (IMR) units allow real-time imaging in physiological positions and during muscular exertion. This study aimed to develop an IMR imaging technique to aid differentiation of the conditions.
Methods Ten patients (eight male, two female) were studied in a 0·5-T General Electric Signa SP10 IMR apparatus. Three had obvious inguinal hernias, one a cord haematoma following previous hernia repair and six occult groin pain without physical signs. Static imaging (T1/T2 fast spin echo (FSE), fast gradient recalled (FSPGR) and short tau inversion recovery (STIR)) was performed with the patient supine for detailed anatomical examination and differentiation of structural from inflammatory lesions. Dynamic real-time imaging (FSPGR, acquisition time 2 s) was then performed with the patient supine and kneeling at rest and during a Valsalva manoeuvre.
Results All patients tolerated the procedure. The sac and defect in the fascia transversalis (FT) were clearly seen in T1 FSE and FSPGR images in the three obvious hernias. The sacs could be seen moving in and out of the defect on dynamic imaging. STIR images were normal. The cord haematoma was differentiated from recurrent hernia by a normal FT and high signal on T2 and STIR imaging. Of the remaining six patients without physical signs imaging revealed one indirect sac in a 30-year-old man which was confirmed at surgery. In one man (aged 31 years) both imaging and surgical exploration revealed no abnormality. The remaining two men (aged 29 and 32 years) had high STIR signals in the posterior rectus, consistent with muscular injury, and no hernial defect. The remaining two women (aged 43 and 57 years) had high STIR signals at the inguinal ligament's insertion on the pubis. These patients were treated conservatively.
Conclusion This study has shown that dynamic IMR imaging can detect and differentiate both clinically apparent and occult groin hernias from musculotendinous injuries. This may reduce the negative surgical exploration rate for such patients in the future.

Incidence of anal sphincter injury during childbirth has been overestimated

A. Varma, J. Gunn, S. W. Lindow* and G. S. Duthie, *Academic Surgical Unit, Castle Hill Hospital, Cottingham and *Academic Department of Obstetrics and Gynaecology, The University of Hull Postgraduate Medical School, Hull, UK*

Background Anal sphincter injury is thought to be present in nearly half of multiparous women who have had vaginal deliveries. Symptoms of such trauma are thought to affect nearly a quarter of multiparous women. This not borne out by current clinical practice.
Methods Eighty pregnant women were assessed antenatally using a symptomatic questionnaire, endoanal ultrasonography and anorectal manometry. They were re-evaluated between 6 and 12 weeks after delivery. All examinations were carried out by the same investigator. All modes of delivery were encountered.
Results Antenatally, there were no instances of faecal urgency or incontinence. Sonography revealed intact sphincters in all women and anal canal resting pressure and squeeze pressure (MSP) were within this laboratory's normal range. Two women reported postnatal faecal urgency; there were no new sphincter defects identified and postnatal manometry results were not significantly different to antenatal values.

Over a 6-week period and using the same methods of evaluation, a further 159 women were assessed within 72 h of delivery. Of this group, one woman developed faecal urgency but there were no reports of faecal incontinence. No third-degree tears occurred.

	Vaginal ($n = 114$)	Forceps ($n = 6$)	Caesarian section ($n = 39$)
Sonographic defects	10 (8·8)	5	0

Values in parentheses are percentages

Median MSP was significantly lower in the 15 women who sustained an anal sphincter injury compared with that in the 144 who did not (interquartile range 35–58) *versus* 78 (65–103) cmH$_2$O; $P < 0·0005$).
Conclusion These results indicate that anal sphincter trauma is an uncommon complication of vaginal delivery and symptoms of sphincter dysfunction affect less than 1 per cent of these deliveries. They provide compelling evidence that previous work has overestimated the incidence and should be updated.

Prognostic significance of flap recurrence following mastectomy for breast cancer

G. J. Byrne, C. S. Bronder, R. Swindell, L. Ashcroft, A. Howell and N. J. Bundred, *University Hospital of South Manchester, Manchester, UK*

Background The management of flap recurrence after mastectomy for breast cancer remains controversial.
Methods Between 1976 and 1991, 3310 mastectomies were performed for breast cancer in one unit. An overall recurrence rate of 9·7 per cent was observed with a mean follow-up of 12·2 (range 5–20) years. Flap recurrences following mastectomy for T_1–T_3 tumours without radiotherapy were identified ($n = 256$) and were examined to determine the factors predicting survival after flap recurrence. Single spot recurrence was treated by simple excision whereas those with multiple spot and field change recurrence received radiotherapy and systemic hormone therapy or chemotherapy. Statistical analysis was by χ^2 test or Student's *t* test.
Results Nodal status at presentation ($P < 0·05$), time to recurrence and presence of concurrent disease influenced survival. Five-year survival for women with concurrent disease at the time of flap recurrence (45 per cent) was poor compared with that in women without concurrent disease (55 per cent) ($P < 0·0001$). Early recurrence (within 12 months of primary surgery) correlated with poor survival ($P < 0·0001$) even allowing for concurrent disease ($P < 0·001$). The type of recurrence (single spot, multiple spot or field of change) did not influence survival and the frequency of concurrent disease with flap recurrence did not depend on the time interval between diagnosis and recurrence.
Conclusion Flap recurrence occurring in the first year following mastectomy for breast cancer predicts poor survival. All flap recurrences have a high chance of concurrent systemic disease and therefore all require systemic therapy.

Importance of negative microscopic margins in the multimodality therapy of oesophageal cancer

E. D. Mulligan, T. N. Walsh, B. Dunne, T. Purcell, M. Griffin, N. Noonan, D. Hollywood, N. Keeling, J. V. Reynolds and T. P. J. Hennessy, *Departments of Surgery, Gastroenterology and Pathology, St James Hospital, Dublin, Ireland*

Background Positive microscopic margins after major cancer surgery for cure adversely affect prognosis. Multimodal therapy (neoadjuvant chemoradiotherapy) prolongs survival in patients with oesophageal cancer compared with surgery alone. It is possible that the benefit of this neoadjuvant approach is in part due to reduced involvement of resection margins and multimodal therapy may alter the disease course when resection margins are involved.

Methods A pathological re-review was performed of 212 patients with oesophageal carcinoma who underwent multimodal therapy ($n = 104$) or surgery alone ($n = 108$), as part of randomized clinical trials. Patients within both groups with microscopic margin involvement were compared for disease recurrence.

Results Margins were microscopically involved in 13 per cent of patients treated by multimodal therapy compared with 38 per cent of those who had surgery ($P = 0\cdot0001$). Twenty-six per cent had a complete pathological response. At a median follow-up of 16 months, patients with clear margins had a recurrence range of 43 per cent (multimodal) and 73 per cent (surgery) ($P = 0\cdot0003$). There was significantly reduced recurrence in patients with positive margins receiving multimodal therapy (38 per cent) compared with patients who had surgery only (89 per cent) ($P = 0\cdot007$).

Conclusion The benefit of multimodality therapy in patients with clear margins remains highly significant when patients with positive margins are excluded. Neoadjuvant therapy increases the number of curative resections compared with surgery alone. The consequences of involved margins are also reduced, with decreased rates of recurrence, suggesting that the neoadjuvant approach may alter the biology of residual tumour cells.

Adenoviral targeted delivery of a suicide gene to the liver: an antineoplastic strategy

D. Evoy, E. A. Hirschowitz, H. A. Naama, M. D. Lieberman, R. G. Crystal and J. M. Daly, *Department of Surgery, The New York Hospital–Cornell Medical Center, New York, USA*

Background Cytosine deaminase (CD) is a bacterial enzyme that converts the non-toxic agent 5-fluorocytosine (5-FC) to the active chemotherapeutic agent 5-fluorouracil (5-FU). Adenoviral vector (Ad.) containing the CD transgene (Ad.CD) can be used to generate high local concentrations of 5-FU, when combined with systemic 5-FC administration. Using this strategy in a flank tumour model of murine pancreatic cancer the authors have previously demonstrated limited efficacy *in vivo* after direct intratumoral injection of Ad.CD. It was postulated that efficacy is limited because of efflux of Ad. from the tumour into the circulation after direct intratumoral injection, followed by preferential uptake of circulating Ad. by the liver, which has numerous Ad. receptors. It was hypothesized that Ad. hepatotropism could be used to treat hepatic tumours using the Ad.CD, 5-FC strategy.

Methods Mice were randomized into four groups ($n = 6$). Solitary hepatic tumours were established by injecting 10^5 Pan02 cells into the right lobe of liver. At 48 h Ad.CD was administered intravenously. At 72 h 5-FC was administered daily for 6 days. Mice were killed on day 15, and tumour growth compared with that in controls.

Results The figure shows the effect of Ad.CD on solitary hepatic tumour growth. Treatment with Ad.CD and 5-FC resulted in significant inhibition in the growth of Pan02 within the liver ($P < 0\cdot005$, analysis of variance).

Conclusion These data demonstrate that adenoviral hepatotropism may have potential use for the treatment of hepatic tumours.

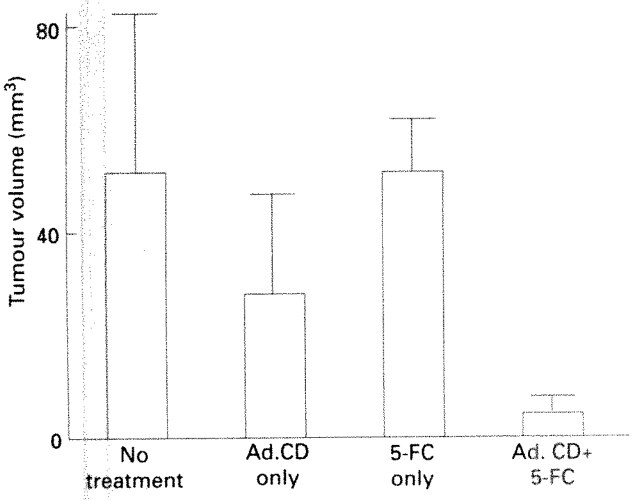

Fig. 1

Fluorescence detection of dysplasia and cancer

M. A. Jahan, I. S. Tait, E. L. Newman and A. Cuschieri, *Department of Surgery, Ninewells Hospital and Medical School, Dundee, UK*

Background 5-Aminolaevulinic acid (ALA) is a fluorescent photosensitizer which has been used to enhance the early detection of cancer and dysplasia with encouraging results. However, it has not been evaluated in the upper gastrointestinal tract where it may aid the endoscopic surveillance of precancerous conditions such as Barrett's oesophagus. The result of an ongoing study of ALA-induced fluorescence in the upper gastrointestinal tract is reported.

Methods Informed consent from patients and local ethics committee approval for the study was obtained. Thirteen patients with histologically confirmed mucosal cancer (eight oesophageal, five gastric) undergoing surgery were studied. Each patient received oral ALA 3–$20\,\mathrm{mg\,kg^{-1}}$ 4–9 h before surgery. Fluorescence was stimulated on specimens and correlated with histology (gold standard). Cancer and severe dysplasia were grouped together as abnormal; Barrett's metaplasia was grouped with normal.

Results The spectroscopic characteristics of fluorescence confirmed tissue uptake of ALA. There were 105 random biopsies from fluorescent and non-fluorescent mucosa (40 normal, 12 Barrett's, eight severe dysplasia and 45 cancer). All biopsies from normal and Barrett's mucosa exhibited fluorescence and all except one specimen of severe dysplasia and five cancers did not fluoresce. Based on this, the sensitivity and specificity of negative fluorescence for predicting cancer and severe dysplasia were 89 per cent and 100 per cent respectively.

Conclusion Previous studies in the skin, lung and bladder have demonstrated selective fluorescence in abnormal tissues. However, in this study fluorescence was absent in the vast majority of abnormal mucosas and present in all normal mucosa samples. The presence or absence of fluorescence predicted cancer and severity with a high degree of accuracy. Therefore, ALA-induced fluorescence may have a potential role in the endoscopic surveillance of patients at a high risk of developing upper gastrointestinal cancer.

Tumour length predicts response to neoadjuvant chemoradiotherapy in oesophageal adenocarcinoma

E. D. Mulligan, T. N. Walsh, B. Dunne, T. Purcell, M. Griffin, N. Noonan, D. Hollywood, N. Keeling, J. V. Reynolds and T. P. J. Hennessy, *Departments of Surgery, Gastroenterology and Pathology, St James Hospital, Dublin, Ireland*

Background Multimodality therapy (neoadjuvant chemoradiotherapy) confers a survival advantage compared with surgery alone in oesophageal adenocarcinoma. This management strategy could be further optimized if the factors predicting response or resistance to this neoadjuvant approach were elucidated. With this aim a detailed clinical, pathological and treatment re-review was performed, comparing neoadjuvant responders with non-responders.

Methods Patients ($n=63$) were categorized as responders ($n=32$) or non-responders ($n=31$) to multimodality therapy based on pathological evaluation of the resected specimen. Responders (T_0N_{0-1}, pT_1N_{0-1}, pT_2N_0) were compared with non-responders (pT_2N_1, pT_3N_{0-1}) for the following variables: age, sex, initial tumour length and differentiation, associated intestinal metaplasia, weight loss (more than 5 per cent before treatment), initial serum albumin level, and post-treatment radiation fibroblasts, and tissue and vascular fibrosis.

Results Initial tumour length (mean 4·2 (responders) *versus* 6·6 cm (non-responders); $P=0{\cdot}0063$, Wilcoxon test) was the sole factor significantly associated with lack of response to the neoadjuvant regimen. The presence and intensity of post-treatment vascular and fibroblast changes ($P=0{\cdot}3$, Fisher's exact test) did not correlate with response.

Conclusion The mural extent of tumour was significantly associated with treatment response. This may reflect a tumour–host relationship for larger tumours promoting catabolism and countering effective treatment responses.

Cytokine gene polymorphism and disease severity in acute pancreatitis

J. J. Powell, J. A. Ross, K. C. H. Fearon and A. K. Siriwardena, *University Department of Surgery, Royal Infirmary of Edinburgh, Edinburgh, UK*

Background Monocyte proinflammatory cytokine secretion mediates disease severity in acute pancreatitis. Cytokine secretion is determined by a combination of environmental and genetic factors. Polymorphisms identified in the tumour necrosis factor (TNF) and interleukin (IL)-1 gene loci correlate with levels of monocyte cytokine secretion *in vivo* and are markers of disease severity in inflammatory conditions. For each condition allele 2 appears important. This study assessed whether these cytokine gene polymorphisms correlate with disease severity in acute pancreatitis.

Methods Leucocyte DNA was isolated from a consecutive series of 124 patients with acute pancreatitis. Molecular techniques were used to determine TNF, IL-1β and IL-1 receptor antagonist genotypes. Disease severity as defined by Atlanta criteria was mild in 78, severe in 42 and four had local complications alone. The aetiological agent was gallstones in 46, alcohol in 42, idiopathic in 22 and 14 'other'. Statistical analysis was by χ^2 test (contingency tables for categorical data).

Results There were no significant differences in genotype frequency distributions nor were there significant differences in the distribution of TNF allele 2, IL-1β allele 2 and IL-1 receptor antagonist allele 2. There was no significant difference in the distribution of these alleles between patients with mild disease and those with severe disease.

Conclusion These results show no association between the cytokine gene polymorphisms studied and disease severity in acute pancreatitis.

Membrane-type matrix metalloproteinase 1 expression in gastric cancer: a new target for therapy

G. Tierney, H. M. Collins, J. H. Scholefield and S. A. Watson, *Department of Surgery, University Hospital, Nottingham, UK*

Background The matrix metalloproteinases (MMPs) are a family of proteolytic enzymes which regulate extracellular matrix turnover and are implicated in tumour growth and metastasis. Their inhibition is an attractive therapeutic concept. Studies of broad-spectrum MMP inhibitors (MMPIs) in advanced gastric cancer have been limited by side-effects. A selective inhibitor might be more efficient. Reverse transcriptase–polymerase chain reaction was used to quantify the relative amounts of MMPs, membrane-type MMPs (MT-MMPs) and tissue inhibitors of MMP (TIMPs) in gastric tumours and the findings were confirmed using gelatin zymography.

Methods Gastric carcinoma tissue and normal mucosa were taken from 20 resections. Messenger RNA (mRNA) was extracted and reverse transcribed to complementary DNA. Competitive polymerase chain reaction was performed with a gene-specific external standard. Results were normalized to glyceraldehyde-3-phosphate dehydrogenase. Zymography was used to show the active and inactive forms of MMP-2 and MMP-9.

Results

mRNA	Median tumour	Median normal	P*
MMP-2	$7{\cdot}4\times10^{-7}$	1×10^{-8}	0·0166
MMP-9	$5{\cdot}8\times10^{-6}$	1×10^{-8}	n.s.
MT-MMP-1	$6{\cdot}5\times10^{-4}$	1×10^{-8}	0·0267
TIMP-1	$5{\cdot}3\times10^{-2}$	1×10^{-8}	n.s.
TIMP-2	$1{\cdot}3\times10^{-3}$	$1{\cdot}8\times10^{-3}$	n.s.

n.s., Not significant. *Wilcoxon test

Gelatin zymography showed both forms of MMP-2 and MMP-9 in the tumour samples but inactive species only in the normal mucosa.

Conclusion These techniques give a relative level of each enzyme within a tumour sample. Comparing tumour with normal tissue reveals a significant difference for MMP-2 and its activator MT-MMP-1. Zymography demonstrates active MMP-2 in the tumours only. An appropriate MMPI might be one specifically against MT-MMP-1. This would prevent the subsequent activation of pro-MMP-2, which has a well established role in the process of tumour growth and metastasis.

TPR-MET oncogenic rearrangement is involved early in gastric carcinogenesis

S. Ramesh, S. McMillan, C. Chadwick and P. McCulloch, *Department of Surgery, University of Liverpool, Liverpool, UK*

Background c-*met*, which encodes the hepatocyte growth factor receptor, can occur in a truncated mutant form spliced to a translocated promoter region (TPR-MET). This form of the receptor is constitutively activated, and is widely believed to be important in carcinogenesis, largely from evidence obtained *in vitro* and transgenic expression in mice. The relative frequency of TPR-MET expression in human gastric carcinomas and normal mucosa is unknown. TPR-MET messenger RNA expression in gastric carcinomas, associated 'normal' mucosa and mucosa from patients with histologically and bacteriologically normal stomachs was studied.

Methods Amplifiable complementary DNA was obtained by reverse transcription of transfer RNA extracted from *N*-methyl-*N*′-nitroso-guanidine human osteosarcoma cells, 35 gastric cancers, 28 associated 'normal' and 18 histologically normal stomachs. 'Hot-start' nested polymerase chain reaction (PCR) was performed, and the products electrophoresed, stained and examined under ultraviolet light. The PCR products were sequenced.

Results Results are shown in the *Table*.

	TPR-MET positive	TPR-MET negative	*P*
Gastric cancer ($n = 35$)	26	9	
Associated normal mucosa ($n = 28$)	19	9	0·13*, 0·26†
Normal mucosa ($n = 18$)	8	10	0·04

*Fisher's exact test, †Paired *t* test

Conclusion TPR-MET rearrangement is found in a high proportion of gastric cancers and associated non-malignant mucosa. It is frequently present in normal mucosa without *Helicobacter pylori* infection. These findings implicate TPR-MET in the very early stages of human gastric carcinogenesis.

Reduction in membranous expression of β-catenin predicts poor survival in gastric cancer

S. Ramesh and P. McCulloch, *Department of Surgery, University of Liverpool, Liverpool, UK*

Background β-catenin, a component of the E-cadherin–catenin cell adhesion complex, also plays a separate intracellular signalling role, interacting with APC (adenomatous polyposis coli) protein. Intracellular accumulation of β-catenin is common in colorectal neoplasia. β-catenin abnormalities are associated with poor survival in gastric cancer, but previous studies have not differentiated between membrane-associated and intracellular β-catenin. The aim of this study was to determine which type of β-catenin expression abnormalities correlate with survival in gastric cancer.

Methods Immunoperoxidase staining of paraffin-embedded sections from 40 gastric cancers was performed for E-cadherin, and α- and β-catenins using microwave unmasking and a biotin–avidin technique. Clinical data were obtained from case records.

Results Abnormalities of intracellular β-catenin staining were rare in gastric cancer (two of 40). Reduced membranous expression occurred in ten of 12 diffuse and eight of 28 intestinal tumours ($P = 0{\cdot}0014$). It was associated with poor differentiation ($P = 0{\cdot}0015$) and short survival ($P = 0{\cdot}032$), but not with age, sex, tumour size or nodal status. Reduced E-cadherin membrane expression was associated with lymph node metastasis ($P = 0{\cdot}02$). Neither E-cadherin nor α-catenin expression correlated with survival.

Conclusion Reduced membranous expression of β-catenin predicts poor prognosis in gastric cancer, whilst ectopic intracellular expression is rare. The apparent differences in β-catenin expression from those found in colonic cancer merit further study.

Loss of heterozygosity on chromosome 17p predicts carcinogenesis progression in patients with Barrett's oesophagus

K. Dolan, J. Gosney, S. J. Walker, R. Sutton and J. K. Field, *Department of Surgery, Royal Liverpool University Hospital, Liverpool, UK*

Background Endoscopic surveillance for adenocarcinoma in patients with Barrett's oesophagus is time consuming and costly, with one cancer detected in every 175 patient-years of follow-up. Genetic abnormalities, including loss of heterozygosity (LOH) at the sites of tumour suppressor genes, have been detected in malignant and premalignant Barrett's oesophagus, and the aim of this study was to determine the feasibility of LOH analysis as a method of identifying which patients with Barrett's oesophagus are at greatest risk of adenocarcinoma, and therefore in greatest need of regular endoscopy.

Methods LOH analysis was performed by polymerase chain reaction and gel electrophoresis on endoscopic biopsies from 48 patients in a Barrett's surveillance programme. Fourteen microsatellite primers located at known or putative tumour suppressor genes on chromosomes 3p (*VHL*), 5q (*APC*), 9p (*CDKN2*), 11p, 13q (*Rb*), 17p (*p53*), 17q and 18q (*DCC*), and shown previously to detect frequent LOH in oesophageal adenocarcinomas, were used in the analysis. The patients were followed endoscopically and histologically for a median of 3·5 years.

Results LOH was detected in nine patients. Three patients with LOH on chromosome 5q or 9p did not progress beyond metaplasia. LOH on chromosome 17p was detected in six patients, all of whom demonstrated carcinogenesis progression (low-grade dysplasia (four patients), high-grade dysplasia (one) and adenocarcinoma (one)).

Conclusion LOH on chromosome 17p identifies patients with Barrett's oesophagus at greatest risk of carcinogenesis progression, and therefore at greatest need of regular endoscopic surveillance.

Intestinal metaplasia at the oesophagogastric junction and cardia in symptomatic patients

J. P. Byrne, S. Bhatnagar*, G. R. Armstrong*, B. Hamid† and S. E. A. Attwood, *University Departments of Surgery and *Pathology, Hope Hospital and †Department of Pathology, Trafford General Hospital, Davyhulme, Manchester, UK*

Background The incidence of adenocarcinoma around the oesophagogastric junction (OGJ) is increasing, and many of these cancers arise in association with areas of intestinal metaplasia (IM). Barrett's oesophagus, characterized by IM over more than 3 cm of the oesophageal lining, is associated with a significantly increased risk of developing adenocarcinoma. Metaplastic changes may involve shorter segments of the lower oesophagus (less than 3 cm) and may not be detected on endoscopy or with routine histological techniques. The aims of this study were to define and compare metaplastic changes at the OGJ with those at the cardia and to identify the true prevalence of Barrett's oesophagus, short-segment Barrett's and microscopic IM in a population of symptomatic patients attending for open access endoscopy.

Methods Some 225 patients had gastroscopy, and any clinically indicated biopsies were taken. In addition, three further sets of endoscopic biopsies were taken from each patient, at 3-cm intervals, from the cardia, the OGJ and the distal oesophagus. These were all examined using haematoxylin and eosin, Alcian Blue/periodic acid–Schiff and high iron diamine/Alcian Blue stains, to define IM.

Results Of 225 patients, eight (3·6 per cent) had carcinoma, eight (3·6 per cent) had conventional long-segment Barrett's oesophagus, 15 (6·7 per cent) showed endoscopic short-segment Barrett's change, and there was no endoscopic Barrett's in 194 (86·2 per cent). Of the latter, 34 (17·5 per cent) had IM at the OGJ and nine (4·6 per cent) at the cardia on haematoxylin and eosin staining. Acid mucin stains detected IM at the OGJ in 135 (69·6 per cent) and at the cardia in 75 (38·7 per cent). Patterns of IM at the OGJ differed from those seen at the cardia. Some 90 per cent of patients with IM detectable by haematoxylin and eosin staining were taking strong acid suppression, compared with 72·8 per cent overall.

Conclusion IM is very common at the OGJ and cardia, with marked differences in incidence and characteristics between the two sites. The relationship of IM at the OGJ to development of carcinoma is yet to be determined.

Endoscopic argon beam plasma coagulation in the restoration of squamous lining in Barrett's oesophagus

J. P. Byrne, G. R. Armstrong* and S. E. A. Attwood, *University Departments of Surgery and *Pathology, Hope Hospital, Manchester, UK*

Background Barrett's oesophagus is associated with a significantly increased risk of development of oesophageal adenocarcinoma. Replacing columnar epithelium by the normal squamous lining in this condition offers the possibility of decreasing risk of degeneration to invasive adenocarcinoma. This study aimed to establish the feasibility of argon beam plasma coagulation (ABPC), in conjunction with control of gastro-oesophageal reflux, to restore the squamous lining.

Methods Some 28 patients with Barrett's oesophagus (four low-grade dysplasia, three high-grade) were recruited from the authors' surveillance programme, and underwent endoscopic ABPC. Gastro-oesophageal reflux was controlled with antireflux surgery in four patients and a proton pump inhibitor in 24.

Results Twenty-one patients have completed treatment, with macroscopic replacement of the columnar lining by squamous epithelium, and have been followed for a median of 4 (range 3–12) months. Four patients are still in treatment and one patient has withdrawn from the study. Two oesophageal perforations, with one death of a patient with high-grade dysplasia who was unfit for oesophageal resection, occurred early in the study. Histological confirmation of squamous replacement has been sought, and found in 12 patients to date. In five patients, the squamous lining was associated with nests of underlying intestinal metaplasia. Standard doses of proton pump inhibitor were insufficient to control acid reflux in four patients, and needed to be increased.

Conclusion ABPC, in conjunction with adequate control of gastro-oesophageal reflux, allows squamous regrowth in both benign and dysplastic Barrett's oesophagus. Despite theoretical safety advantages of ABPC over techniques such as laser, oesophageal perforation may occur with this technique. The significance of foci of intestinal metaplasia underneath normal squamous epithelium is not yet clear. ABPC in 'uncomplicated' Barrett's oesophagus cannot yet be recommended until long-term follow-up of a cohort of cases so treated is able to show a decreased incidence of, and mortality rate associated with, adenocarcinoma.

Angiogenesis as a marker of recurrence in rectal carcinoma

A. G. Heriot, S. Edwards*, C. Finlayson* and D. Kumar, *Departments of Colorectal Surgery and *Histopathology, St George's Hospital, London, UK*

Background Angiogenesis is important in the development and spread of malignant tumours. The aim of this study was to investigate the significance of tumour microvascular density (MVD) in the recurrence of rectal carcinoma following curative surgery.

Methods Sections (4 μm) stained with antifactor VIII antibody were obtained from tumour blocks from the resection specimens of 31 patients who had undergone 'curative' resection of rectal carcinoma and developed tumour recurrence and of 24 patients who remained tumour free 5 years after surgery. Antifactor VIII antibody stains endothelial cells and allows identification of blood vessels. Microvessel counts at the invading tumour edge were made in six 200× fields (20× objective and 10× ocular) by two independent observers.

Results MVD increased with tumour stage. Across the stages in the no-recurrence group, there was a significant increase in MVD from Dukes A to C ($P<0·05$). This difference between Dukes A and C tumours was lost in the recurrence group ($P<0·32$). Overall, MVD was significantly higher in patients developing recurrence.

	Microvascular density			
	No recurrence	Recurrence	P*	P†
Overall	24·5(6·4)	30·7(9·3)	0·007	0·0007
Dukes A ($n=9$)	19·6(3·7)	27·5(4·9)	0·026	0·078
Dukes B ($n=21$)	25·3(6·7)	27·5(5·3)	0·42	0·30
Dukes C ($n=25$)	26·3(6·3)	33·7(11·4)	0·088	0·004

Values are mean(s.d.). *Unpaired t test; †paired t test

Conclusion This study demonstrates that MVD increases with tumour stage and is a significant marker of tumour recurrence. The behaviour of Dukes A tumours above a certain MVD begins to parallel that of Dukes C tumours in terms of recurrence.

Isolation of novel antibodies to colorectal tumour markers using a bacteriophage-display library

J. Greenman, K. P. Topping and J. R. T. Monson, *Academic Surgical Unit, University of Hull, Hull, UK*

Background Bacteriophage-display technology can be used to isolate antibody specificities to both immunogenic and non-immunogenic antigens in their native state. Potentially, antibodies to novel, highly specific, colorectal tumour-associated antigens could be isolated by probing the tumour cell surface with a phage-display library.

Methods A whole cell-based panning technique to generate colorectal tumour-specific antibodies is described. The synthetic Nissim antibody phage-display library was individually panned against two colorectal tumour cell lines, HT29 and LoVo. Following the initial panning, the library was immediately panned against a breast carcinoma cell line (T47D) to remove specificities reacting with common antigens. Two further rounds of panning against the individual colorectal cell lines were conducted. Whole cell enzyme-linked immunosorbent assay was used to select individual clones showing high absorbance with the colorectal cell line and low absorbance with T47D. These results were confirmed by fully automated cell-count system (FACS) analysis.

Results

	Absorbance (A_{405}–A_{690})		FACS (% positive staining)	
Clone	HT29	T47D	HT29	T47D
AF8	0·544	0·003	47·1	6·2
AF11	0·549	0·008	25·3	6·9
BC9	0·586	0·032	75·4	6·7

Further FACS analysis with a panel of six colorectal and three breast cell lines confirmed colorectal-specific and cell line-specific clones. Interestingly, none of these cell line-specific clones binds primary colorectal tumour sections from snap-frozen tissue.

Conclusion Having developed a successful whole cell-based panning method it is intended to repeat this procedure using primary colorectal tumour cells.

Regulation of matrix metalloproteinase (MMP)2 and its activator membrane-type MMP in colorectal cancer

M. K. Roy, D. Grimshaw, D. L. Jones, A. Baker†, G. T. Williams* and P. D. Carey, *Departments of Surgery and *Pathology, University of Wales, College of Medicine, Cardiff and †Department of Cardiology, Bristol Heart Institute, Bristol, UK*

Background Amongst the broad family of matrix metalloproteinases (MMPs), MMP-2 plays an important role in the degradation of the basement membrane. The membrane-type MMP (MT-MMP) is the sole activator of pro-MMP-2 and is believed to be liberated by cancer cells. The nature of interaction between the colonic cancer cells and fibroblasts which brings this about was explored by co-culturing the two cell lines.

Methods The fibroblast cell line KB16F and colonic cancer cell lines HT115 and HRT18 were grown in separate flasks. Some 0·6 million tumour cells were added to the fibroblasts and incubated. In the second experiment, the conditioned medium from a cancer cell line was added to the fibroblast cell line and the cells were incubated for a similar duration. Both the experiments were performed for 72 h, at the end of which the conditioned medium was subjected to standard sodium dodecyl sulphate–polyacrylamide gel electrophoresis gelatin zymography. The lytic bands were sized against standard markers and MMP-2 was identified. The cells were subsequently scraped off and subjected to Northern blot analysis and probed with complementary DNA probes of MMP-2 and MT-MMP.

Results The fibroblasts constitutively expressed pro-MMP-2 and active MMP-2 while the colonic cell lines did not produce any MMP. Northern blot analysis revealed MMP-2 and MT-MMP RNA in fibroblasts only. On co-culture, and also when the fibroblasts were exposed to tumour-conditioned medium, there was an increased activation of pro-MMP-2. This was associated with translational upregulation of MMP-2 and MT-MMP messenger RNA (mRNA) in the fibroblasts.

Conclusion These data suggest that expression of fibroblast MMP-2 is under translational regulation and is intimately associated with MT-MMP mRNA expression. This co-expression of MMP-2 and MT-MMP in fibroblasts questions the popular belief that MT-MMP is expressed solely by cancer cells.

Loss of perivascular nerves in the submucosa adjacent to colorectal cancer

V. Chamary, T. Robson*, M. Loizidou, P. B. Boulos, I. Taylor and G. Burnstock*, *Departments of Surgery and *Anatomy, University College London Medical School, London, UK*

Background Various cancers lack perivascular innervation. However, blood vessel innervation has been observed in tissue adjacent to tumours, but no quantitative study exists.

Methods The perivascular innervation of arterioles in colorectal cancer ($n = 15$) and adjacent submucosa was studied using a panel of immunohistochemical markers of transmitters: neuropeptide Y (NPY), tyrosine hydroxylase (TH), vasoactive intestinal peptide (VIP), substance P (SP) and calcitonin gene-related peptide (CGRP). Immunoreactivity was compared with that of normal colonic tissue (controls). Furthermore, distance from the tumour edge over which immunoreactivity was reduced was measured.

Results The absence of perivascular nerves within colorectal cancers was confirmed, and in addition loss of perivascular nerves in areas of submucosa adjacent to cancers was noted. The loss was progressively greater with advancing tumour stage (Dukes A to C) for TH, NPY and VIP. The pattern of loss varied for different transmitters: in the submucosa of Dukes A cancers, a mean 5 per cent of the total number of arterioles showed TM immunoreactivity (controls, 75 per cent), 69 per cent showed NPY immunoreactivity (controls, 95 per cent) and 23 per cent showed VIP immunoreactivity (controls, 57 per cent). For Dukes B submucosal arterioles, immunoreactivity dropped to 7, 12 and 20 per cent and for Dukes B to 0, 9 and 17 per cent (TH, NPY and VIP respectively). There was no decrease in SP in Dukes A submucosa (40 per cent) compared with controls, but immunoreactivity fell in Dukes B (19 per cent) and C (0 per cent). CGRP immunoreactivity was never above 4 per cent. Reduced NPY immunoreactivity was observed over a mean of 4·3 mm (Dukes A/B, 1·3 mm; Dukes C/D, 5·7 mm) and 4·5 mm for VIP (Dukes A/B, 3·9 mm; Dukes C/D, 6·0 mm). TH and SP measurements did not return to normal within the available tissue (8·3 mm).

Conclusion There exists a progressive loss of neurotransmitters with stage. This suggests the tumour itself may influence neural integrity, perhaps via the secretion of humoral factors.

Colorectal cancer vaccine 105AD7 increases tumour infiltration of CD25-positive lymphocytes

C. A. Maxwell Armstrong, L. G. Durrant, R. A. Robins, A. M. Galvin, J. H. Scholefield and J. D. Hardcastle, *Department of Surgery, University Hospital, Nottingham, UK*

Background The anti-idiotypic monoclonal antibody 105AD7 mimics an antigen present on 80 per cent of colorectal cancer cells. Phase I studies have confirmed that the vaccine is non-toxic. Work previously presented to the Society has shown increased expression of the interleukin 2 receptor, CD25, on immunohistochemical staining of tumour sections from patients receiving the vaccine before surgery. The aim of this work was to assess expression of the activation markers CD25, human leucocyte antigen (HLA) DR and CD69 on lymphocytes at the tumour site of patients with colorectal cancer receiving 105AD7, and their controls, using flow cytometry.

Methods Tumour samples were taken prospectively from the resection specimens of 54 patients. Nineteen patients had received 105AD7 before surgery, while 35 had not. Samples were disaggregated with collagenase/DNAase and lymphocytes were separated out using a discontinuous Percoll gradient. Lymphocyte preparations were labelled with CD3, CD4, CD25, HLA-DR and CD69 and analysed blindly on the FACScan.

Results Results were available for 16 of 19 immunized patients and 26 of 35 controls. The percentage of lymphocytes expressing CD25 was higher in patients receiving 105AD7 before operation (8 *versus* 4 per cent; $P = 0{\cdot}003$), as was expression of CD3/CD69 (66 *versus* 58 per cent; P not significant) and CD4/HLA-DR (26 *versus* 23 per cent; P not significant).

Conclusion Increased expression of CD25 at the tumour site of patients who received 105AD7 suggests a population of activated lymphocytes and confirms results obtained using immunohistochemistry. This may confer a survival advantage on patients who receive the vaccine. Further work needs to be done.

Relationship between circulating tumour cell cluster prevalence and stage in colorectal cancer

R. Q. Wharton, S. K. Jonas, C. Stupnicka, M. Henry and T. G. Allen-Mersh, *Department of Surgery, Imperial College School of Medicine, Chelsea and Westminster Hospital, London, UK*

Background The authors have previously demonstrated that reverse transcriptase–polymerase chain reaction (RT–PCR) can be used to identify complementary DNA (cDNA) coding for carcinoembryonic antigen (CEA) in the circulation of patients with colorectal cancer, and that multiple blood sampling increases the probability of detecting a cancer cell cluster. Possible differences in cell cluster prevalence between primary and metastatic or node-negative and node-positive primary cancer have been examined.

Methods Some 14 ml peripheral venous blood were sampled via a cannula from patients with colorectal cancer, after discarding the first 5 ml, three times at 1-min intervals. After the addition of erythrocyte lysis buffer, total RNA was extracted by conventional methods from the remaining cells and subjected to RT–PCR

using specific primers for cDNA CEA (29 cycles). The PCR products were run on electrophoresis gels. The PCR product was confirmed by Southern blotting using an oligoprobe which lies between the two primers. Forty-three patients without known carcinoma used as controls were all found to be negative.
Results There was a significant increase ($P < 0{\cdot}05$, Fisher's exact test) in RT–PCR positivity of metastatic (24 of 27) compared with primary (17 of 26) tumour samples, but no significant difference between Dukes A and B (11 of 16) compared with C (six of ten) primary tumour samples. Similarly there was a significant increase ($P < 0{\cdot}05$, Kendall's tau test) in cell cluster prevalence of metastatic (median 2 (interquartile range 1–3)) compared with primary (1 (0–2)) tumour samples, but no significant difference between Dukes A and B (1 (0–2)) compared with C (1 (0–3)) lesions.
Conclusion The increase in cell cluster positivity and prevalence in metastatic but not in node-positive primary carcinoma suggests that the presence of circulating cancer cells may relate to factors other than biological behaviour, such as tumour bulk and hepatic portal filtration.

Genotoxicity of 5-aminolaevulinic acid

M. A. Jahan, I. S. Tait, E. L. Newman and A. Cuschieri, *Department of Surgery, Ninewells Hospital, Dundee, UK*

Background 5-Aminolaevulinic acid (ALA) is a prodrug for the fluorescent photosensitizer protoporphyrin IX (PpIX) used for diagnosis and treatment of epithelial tumours. PpIX interacts with light to induce photodynamic tissue damage including DNA damage. However, there have been recent reports of ALA-induced DNA damage in the absence of light. This is of concern in the diagnostic use of ALA in otherwise healthy individuals and has been evaluated in an *in vitro* cell culture model and an *ex vivo* clinical model.
Methods MCF7 cells were incubated in ALA 0–1 mmol l^{-1} for 5 h in the dark. Cells were disaggregated and single-cell gel electrophoresis (comet assay) was performed to determine the extent of DNA damage. Oesophageal and gastric biopsies from ALA-sensitized patients were similarly disaggregated and the comet assay performed.
Results The extent of DNA damage in MCF7 cells was statistically significant at ALA 1 mmol l^{-1} compared with control ($P < 0{\cdot}001$). At ALA 1 mmol l^{-1}, the mean(s.d.) damaged DNA content was 7·0(0·3) per cent compared with 3·2(0·1) per cent in the absence of ALA (negative control), and 26·6(0·5) per cent in the presence of ALA plus light (positive control). The damaged DNA content in mucosal biopsies was 3·5(0·2) per cent in controls and 3·4(0·3) per cent for patients pretreated with ALA 20 mg kg^{-1} ($P = 0{\cdot}3$).
Conclusion ALA causes a dose-dependent dark genotoxicity in cell culture. However, DNA damage was not detected in biopsies from patients receiving a clinically relevant dose of ALA 20 mg kg^{-1}. The result of this study lends support to the continued clinical use of ALA.

Increasing primary tumour vascularity and proliferation does not increase metastasis

M. M. Davies, S. Kaur, P. Carnochan* and T. G. Allen-Mersh, *Department of Surgery, Imperial College School of Medicine, Chelsea and Westminster Hospital, London and *Department of Physics, Institute of Cancer Research, Sutton, UK*

Background Primary tumour vascularity has been shown to correlate with metastasis. The effect of growth factor-induced change in primary tumour vascularity and proliferation on metastasis has been examined.
Methods The spontaneously metastasizing rat tumour K12/TR which proliferates in response to basic fibroblast growth factor (bFGF) was used. K12/TR tumour cells (10^6) were injected subcutaneously into BDIX rats and infused continuously for 28 days with bFGF or saline using an osmotic minipump, and the resulting subcutaneous tumour was then excised. Tumour sections were stained for vascularity (OX-43 antibody) and proliferation (PC10 antibody). Vessel volume, vessel count and proliferation index were determined at ×400 magnification by graticule counting. Blood flow was determined by the autoradiographic ratio of $[^{125}I]$iodoantipyrine activity between the tumour edge and centre. After a further 2 months the animals were killed and the lungs examined for metastases.
Results

	Saline	bFGF	*P*
Primary tumour			
Vessel volume (%)	3·6 (2·5–4·3)	5·9 (5·8–6·2)	0·004
Vessel count (mm^{-2})	35 (34–36)	65 (62–77)	0·008
Blood flow (central tumour : tumour edge ratio)	0·3 (0·3–0·3)	1·1 (0·9–1·2)	0·05
Proliferation index (%)	12 (9–15)	21 (20–23)	0·03
Tumour volume (ml)	1·1 (1·1–1·8)	2·5 (2·1–2·6)	0·02
Lung metastases	9 of 17	11 of 18	0·3

Conclusion An increase in primary tumour vascularity and proliferation was not associated with increased metastasis. The results suggest that metastasis was limited by factors other than primary tumour proliferation and vascularity.

Value of colonoscopic biopsies for genetic analysis

S. B. Sengupta, C.-Y. Yiu and P. B. Boulos, *Department of Surgery, University College London Medical School, London, UK*

Background Patients with hereditary non-polyposis colorectal cancer (HNPCC) have inherited mutations in one of the DNA mismatch repair genes. These individuals develop cancers that generally show microsatellite instability and are prone to synchronous and metachronous colorectal cancers as well as extracolonic cancers. Identification of the precise germline mutation demands screening several genes. However, microsatellite instability status is a useful marker for a defective mismatch repair system and may be of relevance in families that do not conform with the clinical criteria for HNPCC. Microsatellite instability is also a feature of patients at risk of metachronous colorectal cancers. Preoperative knowledge of the genetic abnormality may therefore influence surgical treatment. This study investigated the adequacy of colonoscopic biopsy in genetic analysis.
Methods Six specimens were taken with a colonoscopy forceps and larger tissue specimens were obtained from 13 resected cancers and two villous adenomas, and examined for microsatellite instability at D2S123, D18S58, BAT25, BAT26 and BAT40 by single-stranded conformational polymorphism analysis. Codons 1264–492 of the *APC* gene were also investigated for mutations.
Results None of these tumours showed microsatellite instability. However, the banding patterns of the colonoscopic biopsies and those available from resected specimens were completely consistent for each patient. A somatic mutation of the *APC* gene was detected in all the specimens taken from one tumour.
Conclusion These results suggest that colonoscopic biopsies are sufficiently reliable in defining the genetic make-up of individual colorectal tumours for this investigation to be employed in management.

Expression of cadherin–catenin complex in premalignant gastric mucosal lesions

S. Ramesh and P. McCulloch, *Department of Surgery, University of Liverpool, Liverpool, UK*

Background E-cadherin, β-catenin and α-catenin are normally found at the cell membrane, forming the basis of intercellular adherens junctions. Weak membranous or strong cytoplasmic

expression of these proteins is therefore abnormal, and can occur in gastric cancer. The aim of this study was to determine cadherin and catenin expression in premalignant gastric mucosal lesions.
Methods Paraffin-embedded material from endoscopic biopsies showing dysplasia ($n = 17$), intestinal metaplasia (IM, $n = 17$) or chronic atrophic gastritis (CAG, $n = 25$) were stained for E-cadherin, and α- and β-catenins by immunohistochemical methods and compared with 20 histologically normal biopsies.
Results Abnormal expression of the three proteins was noted as shown in the *Table*.

Expression	Dysplasia	IM	CAG	Normal
E-cadherin (cytoplasmic)				
Strong	12†	7*	0	0
Weak or negative	5	7	25	20
E-cadherin (membranous)				
Strong	9	13	25	20
Weak or negative	8*	1	0	0
α-catenin (cytoplasmic)				
Strong	11†	3	0	0
Weak or negative	5	8	25	20

$^*P<0{\cdot}02$, $^†P<0{\cdot}001$ (χ^2 test with Yates' and Bonferroni correction)

Both dysplasia and IM showed significant cytoplasmic expression of E-cadherin; dysplasia also showed significant cytoplasmic expression of α-catenin and reduced membranous E-cadherin expression.
Conclusion Abnormal expression of E-cadherin and α-catenin increases with increasingly severe premalignant change in gastric mucosa. Further studies are warranted to determine whether these changes define a subset at higher risk of malignant change.

Non-invasive technique to assess hepatic tissue oxygenation using near-infrared spectroscopy

A. El-Desoky, A. M. Seifalian and B. R. Davidson, *University Department of Surgery, Royal Free Hospital and School of Medicine, London, UK*

Background Adequate hepatic tissue oxygenation is vital to the outcome of liver surgery and transplantation. Near-infrared spectroscopy (NIRS) is a non-invasive method for measurement of tissue oxygenation. The aim of this study was to validate NIRS for measurement of hepatic tissue oxygenation.
Methods The study was conducted under a licence granted by the Home Office in accordance with the Animals (Scientific Procedures) Act 1986. Large Landrace pigs ($n = 11$) underwent laparotomy. Hepatic blood flow measurement was done by ultrasonic probes placed around portal vein (PV) and hepatic artery (HA). NIRS was recording continuously oxyhaemoglobin (HbO$_2$), deoxyhaemoglobin (Hb), total haemoglobin (HbT) and differential haemoglobin (HbD). Hepatic vascular inflow occlusion (HVIO) was done in six animals. Reduction of the inspired oxygen fraction ($F_{\mathrm{iO_2}}$) was done in five animals.
Results NIRS measurements with HVIO are shown in the *Table*.

	HA occlusion	PV occlusion	HA and PV occlusion
Hb (μmol l^{-1})	9·2(20·6)	16·0 (55·2)	37·7(109·6)
HbO$_2$ (μmol l^{-1})*	− 49·7(19·6)	− 124·8(55·1)	− 197·2(59·2)
CyOx (μmol l^{-1})*	8·7(6·1)	23·4(9·5)	35·2(8·8)
HbD (μmol l^{-1})*	− 58·8(32·6)	− 140·8(48·1)	− 234·9(103·2)
HbT (μmol l^{-1})†	− 40·5(23·6)	− 108·8(99·2)	− 159·5(142·8)

Values are mean(s.d.) for six pigs. $^*P<0{\cdot}01$, $^†P<0{\cdot}05$ *versus* baseline

A significant correlation was found between the reduction of hepatic blood flow and hepatic HbO$_2$ ($r = 0{\cdot}68$, $P<0{\cdot}05$). With reduction of the $F_{\mathrm{iO_2}}$, a significant correlation was found between HbO$_2$ and Hb and arterial oxygen saturation ($r = 0{\cdot}82$ and $r = -0{\cdot}88$ respectively, $P<0{\cdot}01$).
Conclusion NIRS can be used as a non-invasive method for assessing hepatic tissue oxygenation.

Colonic cancer cell-mediated upregulation of fibroblast-derived matrix metalloproteinase 9 is dependent on a cancer cell membrane component

M. K. Roy, D. Grimshaw, D. L. Jones, A. Baker†, G. T. Williams* and P. D. Carey, *Departments of Surgery and *Pathology, University of Wales, College of Medicine, Cardiff and †Department of Cardiology, Bristol Heart Institute, Bristol, UK*

Background Matrix metalloproteinases (MMPs), which are capable of degrading extracellular matrix, are implicated in tumour invasion and metastasis. Among the broad family of metalloproteinases, MMP-9 has been strongly implicated in the invasion of colonic cancers. Stromal fibroblasts are the principal cells that release MMP-9. The interaction between colonic cancer cells and fibroblasts which upregulates MMP-9 expression was clarified by co-culturing human colonic cancer cells and fibroblasts.
Methods The fibroblast cell line KB16F and colonic cancer cell lines HT115 and HRT18 were grown in separate flasks. Some 0·6 million tumour cells were added to each fibroblast cell type and incubated in serum-free medium. Subsequently, the conditioned medium from the cancer cell line was added to the fibroblast cell lines. In a third experiment, the cells were incubated in tissue culture inserts separated by a 3-μm porous filter which prevents physical contact between the cells but allows chemicals to diffuse freely. Finally, the tumour cells were methanol fixed and co-cultured with fibroblasts. All the experiments were conducted for 72 h, at the end of which the conditioned medium was subjected to standard sodium dodecyl sulphate–polyacrylamide gel electrophoresis gelatin zymography. The lytic bands were sized against standard markers and MMP-9 was identified.
Results The fibroblast cell line and colonic cell line did not produce any MMP-9 under basal conditions. There was an increased expression of fibroblast MMP-9 only when the cells were co-cultured and this was also evident when the tumour cells were methanol fixed. MMP-9 failed to appear when the fibroblasts were exposed to tumour-conditioned medium and also when the cells were incubated in tissue culture inserts.
Conclusion These data suggest that colonic cancer cell-mediated upregulation of fibroblast MMP-9 is due to a cancer cell membrane component.

Influence of intra-abdominal bleeding on peritoneal fibrinolysis and adhesion formation

L. Yong, M. Puttick, J. Hyat, A. O. Mansfield and A. Darzi, *Academic Surgical Unit, Imperial College School of Medicine at St Mary's, London, UK*

Background Intraoperative bleeding potentially promotes adhesion formation because of the presence of increased fibrin deposition between tissue surfaces. The effect of controlled blood loss to the peritoneal cavity was investigated to determine its effect on peritoneal fibrinolysis and adhesion formation following laparoscopic and open bowel manipulation.
Methods Sixty-five male Sprague–Dawley rats were divided to diagnostic laparoscopy (lap) and laparotomy (open), and baseline control groups. Controlled blood loss was simulated by tail-vein venesection of 1·5 ml blood which was evenly injected into the peritoneal cavity. Controls received 1·5 ml saline. Systematic bowel handling and inspection of the peritoneal cavity

was performed in all animals with instruments only. Five rats from each group were killed at 2 and 4 days, and at 2 weeks. Intra-abdominal adhesion scores were measured. Peritoneal fibrinolysis was assessed from samples of parietal peritoneum by measurement of plasminogen activator (PAA) and inhibitor (PAI) activity.

Results

		2 days			
	Baseline	Open + blood	Lap + blood	Open + saline	Lap + saline
PAA (×10^2 units ml^{-1})	13·0(1·0)	32·0(7·0)*	31·0(11·0)*†	32·0(15·0)*	24·0(6·0)*
PAI (units ml^{-1})	12·0(7·7)	7·6(5·7)	9·5(6·1)	7·5(5·8)	10·1(7·[illegible])
Adhesion score	0	0·8(0·4)	1·0(0·7)	0	0·4(0·8)

		4 days			
	Baseline	Open + blood	Lap + blood	Open + saline	Lap + saline
PAA (×10^2 units ml^{-1})	13·0(1·0)	45·0(39·0)*	33·0(11·0)*†	36·0(13·0)*†	28·0(8·0)*
PAI (units ml^{-1})	12·0(7·7)	10·6(5·7)	10·0(3·2)	9·6(5·2)	9·3(3·4)
Adhesion score	0	2·0(0·7)	0·2(0·2)	0·2(0·2)	0·4(0·4)

		2 weeks			
	Baseline	Open + blood	Lap + blood	Open + saline	Lap + saline
PAA (×10^2 units ml^{-1})	13·0(1·0)	22·0(8·0)	16·0(2·0)	17·0(4·0)	17·0(3·0)
PAI (units ml^{-1})	12·0(7·7)	3·8(7·7)	5·2(7·8)	5·3(8·0)	6·8(5·4)
Adhesion score	0	8·4(3·4)	1·6(2·0)‡	2·4(2·0)‡	0·8(1·0)‡

Values are mean(s.d.). *$P < 0·05$ *versus* control, †$P < 0·05$ *versus* 2 weeks (Kruskal–Wallis test); ‡$P < 0·001$ *versus* 2 weeks open + blood (Tukey–Kramer multiple comparisons)

Surgery resulted in a universal rise in PAA at 2 and 4 days which returned to normal at 2 weeks. There was, however, no change in PAI activity. At 2 weeks blood in the peritoneum was associated with a significantly greater adhesion score compared with that in controls which received saline. Moreover, intraperitoneal bleeding during laparotomy resulted in a significantly greater adhesion score than laparoscopy.

Conclusion The presence of blood in the peritoneum in combination with laparotomy synergistically enhances the formation of postoperative adhesions.

Heme oxygenase 1: a potential marker of surgical stress

D. J. Exon, M. J. J. Vesely, R. Motterlini, C. J. Green and S. J. D. Chadwick, *Department of Surgical Research, Northwick Park Institute for Medical Research, Northwick Park and St Mark's Hospital, Harrow, UK*

Background Laparoscopic surgery provides distinct clinical advantages for the patient, yet whether or not it is metabolically less 'stressful' than open surgery remains controversial. Heme oxygenase 1 (HO-1) is a highly inducible stress protein, responsible for the catabolism of cellular heme to biliverdin (a powerful antioxidant) and as a consequence protects the cell from further insult. The aim of this study was to determine if surgical stress induces atrial HO-1 messenger RNA (mRNA) expression and whether the degree of gene expression reflects the apparent difference in 'stress' between laparoscopic and open surgery.

Methods Male Sprague–Dawley rats (weight 400–550 g) were randomized to anaesthetic only, 1 h of carbon dioxide pneumoperitoneum (intra-abdominal pressure 8–10 mmHg) or 1 h laparotomy. The animals were killed and both atria isolated for RNA extraction. Differential reverse transcription–polymerase chain reaction (using β-actin as internal standard) was used to detect and semiquantify the HO-1 mRNA present in 1 μg extracted RNA. The results are expressed as a ratio of the amount of HO-1 mRNA to β-actin mRNA for each group.

Results

	HO-1/β-actin ratio
Control	1·42(0·06)
Pneumoperitoneum	1·45(0·07)
Laparotomy	2·11(0·25)*

Values are mean(s.e.m.) for each group ($n = 6$–7). *$P < 0·05$ *versus* control and pneumoperitoneum (Mann–Whitney U test)

Conclusion Atrial HO-1 expression increased significantly during open surgery, but not during pneumoperitoneum. HO-1 induction may be important in differentiating the degree of surgical stress associated with a particular operative approach.

Rat liver preservation with phosphate-buffered sucrose: demonstration in an isolated perfused liver model

Z. Du, D. Xu, D. J. Potts*, N. Ahmad and J. P. A. Lodge, *Department of Organ Transplantation, St James's University Hospital and *Department of Physiology, University of Leeds, Leeds, UK*

Background Phosphate-buffered sucrose (PBS140) is a clinically proven and inexpensive kidney preservation solution but it has not been fully evaluated in liver preservation. Successful liver preservation for 24 h with PBC140 in a model of isolated perfused rat liver is reported with results comparable to those obtained with University of Wisconsin solution (UW).

Methods Wistar rats (200–250 g) were anaesthetized with intraperitoneal pentobarbitone 50 mg kg^{-1}. After a midline laparotomy, the common bile duct was cannulated with a fine-bore polyethylene catheter. Some 50 units heparin in 2 ml normal saline were injected via the penile vein. The aorta was cannulated and the liver flushed *in situ* with 20 ml Ringer lactate (control), UW or PBS140. Some 5 ml test solution was next perfused via the portal vein. The liver was removed and stored in the flush solution at 40°C. After 24 h of storage, the liver was set up on a recirculating circuit system at 37°C. The basic solution for reperfusion was Ringer lactate to which bovine red cells were added to increase the oxygen carrying capacity and bovine albumin to maintain the oncotic pressure. Taurocholic acid (4·84 per cent) was infused at 5 ml h^{-1} to the inflow system to support bile production. Bile was collected during the reperfusion period. Lactate dehydrogenase (LDH), aspartate aminotransferase (ASAT) and alanine aminotransferase (ALAT) levels were determined after preservation and reperfusion. The concentration of bilirubin in the bile was also measured and the percentage of bile acid used by the liver was calculated.

Results

Test solution	Bile flow (μl per 2 h per g)	Bile acid used in the liver (%)	Bilirubin (mg dl^{-1})	Enzyme (units l^{-1}) ALAT	ASAT	LDH
UW	145(7)	55·2(3·4)	4·41(0·49)	17·0(0·3)*	23·2(5·4)*	179·6(20·4)*
(n = 6)				24·3(1·1)†	30·2(3·5)†	83·5(8·3)†
PBS140	147(16)	50·8(4·5)	6·65(0·74)	33·3(2·8)*	30·1(3·5)*	161·4(15·5)*
(n = 8)				43·9(3·3)†	62·2(5·5)†	181·3(15·6)†
Ringer lactate	45(7)	8·3(2·8)	1·55(0·36)	170·9(29·4)*	224·8(36·3)*	1640·1(132·1)*
(n = 6)				118·2(19·4)†	331·5(34·4)†	1107·4(181·8)†

Values are mean(s.e.m.). *After preservation for 24 h (first flush); †after reperfusion (last flush)

Conclusion These results suggest that PBS140 is worthy of further investigation for preservation of organs other than kidney.

Novel human model of intestinal epithelial regeneration

A. Sattar, B. Angus and F. C. Campbell, *Department of Surgery, University of Newcastle, Newcastle-upon-Tyne, UK*

Background Intestinal epithelial regeneration is central to inflammatory, ulcerative and infective diseases of the intestine, but regulatory mechanisms are obscure. Lack of a suitable model has hampered progress. This study aimed to develop a reproducible model of human intestinal epithelial regeneration.
Methods Human fetal intestinal epithelium at 10–16 weeks' gestational age was retrieved, diced and washed. The epithelial layer was disaggregated by collagenase and dispase, then differentially centrifuged to obtain homogeneous preparations of crypt progenitor epithelium. Epithelial preparations were cultured *in vitro* and grafted subcutaneously (20 μl per graft) to Scid (severe combined immunodeficient) mice. Grafts were retrieved at intervals of 7, 14, 21, 35 and 50 days after transplantation for assessment of morphology and differentiation.
Results Twenty-one of 26 grafts were successful. A temporal sequence of regeneration was shown: by 7 days the epithelium formed an undifferentiated proliferative mass ('blastema' stage), by 21 days there was crypt formation, by 35 days crypt fission and by 50 days cytodifferentiation and villus formation. Cultured cells expressed epithelial markers cytokeratins 8 and 18.
Conclusion This study has developed the first model of human intestinal epithelial regeneration, which may be applied to studies of inflammatory bowel disease.

Effect of malnutrition on gut permeability and septic outcome following major surgery

S. Kanwar, A. C. J. Windsor, P. M. Murchan, S. Elhasani, S. Perry, P. J. Guillou and J. V. Reynolds, *Professorial Surgical Unit, St James's University Hospital, Leeds, UK*

Background Malnutrition in hospitalized patients is prevalent and is associated with an enhanced risk of developing sepsis. Failure of gut barrier function with resultant translocation of bacteria and endotoxin has been incriminated in the pathogenesis of the sepsis response. The relationship between the degree of malnutrition, intestinal permeability and incidence of septic events was investigated in 56 patients undergoing major resectional surgery for oesophageal, gastric and pancreatic cancer.
Methods Preoperative nutritional status was assessed by Nutritional Risk Index (NRI = (1·519 × serum albumin) + 0·417 × (current weight/usual weight) × 100) in all patients. Intestinal permeability (lactulose : mannitol (L : M) ratio) and serum immunoglobulin (Ig) M antiendotoxin (EndoCAb) antibodies were determined before operation (PRE) and on postoperative days 1 and 7 (POD1 and POD7). Thirty-day septic morbidity (intra-abdominal abscess/empyema and pneumonia) was recorded.
Results Degree of malnutrition, intestinal permeability, endotoxin levels and incidence of sepsis are shown in the *Table*.

Degree of malnutrition	L : M ratio PRE	POD1	POD7	IgM EndoCAb (MU ml^{-1}) PRE	POD1	POD7	Sepsis (%)
Well nourished NRI > 97·5 (n = 21)	0·05(0·1)	0·18(0·9)	0·09(0·1)	161(189)	92(97)	235(161)	14
Mildly malnourished NRI 83·5–97·5 (n = 26)	0·09(0·9)	0·19(3·2)	0·08(0·5)	152(67)	83(52)	210(151)	30
Severely malnourished NRI < 83·5 (n = 9)	0·07(0·3)	0·15(0·1)	0·21(0·4)	134(127)	96(45)	223(172)	44

Values are median(s.d.)

Logistic regression analysis did not identify significant association between intestinal permeability, level of endotoxin and the development of sepsis.
Conclusion These data confirm that severely malnourished patients have a higher incidence of sepsis following major resectional surgery compared with non-malnourished patients. Although permeability in the severe group remains raised 7 days after operation, there is no association between the degree of malnutrition and intestinal permeability following major surgery, and thus no clear link with failure of gut barrier function and septic outcome in malnourished patients.

Direct acidification of colonic mucosa by dopamine via D_{1A} receptors

D. C. Winter, A. M. Aherne*, C. J. Vaughan*, D. P. O'Connell*, B. J. Harvey†, J. P. Geibel‡ and G. C. O'Sullivan (introduced by T. P. J. Hennessy), *Departments of Surgery, *Pharmacology and †Cellular Physiology, Mercy Hospital and University College Cork, Cork, Ireland, and ‡Department of Surgery, Yale University, New Haven, Connecticut, USA*

Background Tonometric measurements of colonic and gastric mucosal pH are used to determine splanchnic perfusion. Acidification is assumed to signify poor circulatory responses to dopamine. Colonic mucosa was probed for dopamine receptor subclasses and direct effects of dopamine on cellular pH (independent of oxygenation) were examined.
Methods Receptor subclasses were co-localized with immunohistochemistry and *in situ* hybridization. Cellular pH was recorded using confocal laser imaging of mucosal crypts from the distal colon of adult Sprague–Dawley rats. Crypts were loaded with a pH-sensitive fluorescent probe and perfused with Ringer's solution. Fluorescent emission intensity was expressed as mean(s.e.m.) percentage of the basal value at a dose of 250 nmol l^{-1} for n = 144 (n = number of cells measured per crypt × number of crypts × number of animals). A t test was used for statistical analysis. Ethics committee approval was obtained.
Results D_{1A} receptors were localized to mucosal crypts. Dopamine perfusion produced a cytosolic acidification within a mean(s.e.m.) of 2(0·4) min (47(12) per cent). The action of dopamine was unaffected by: (1) the absence of bicarbonate (acetazolamide and carbon dioxide-free perfusion) (46(6) per cent); (2) α/β-adrenergic receptor blockade (prazosin and propranolol respectively) (48(14) per cent); or (3) protein kinase C inhibition with chelerythrine (49(9) per cent) (all $P > 0·8$). No effect of dopamine was seen following acidification by adenosine 3',5'-cyclic monophosphate (cAMP) with forskolin or by sodium–proton exchange inhibition with ethylisopropylamiloride (both $P > 0·8$).
Conclusion Dopamine directly acidifies mucosal crypt cells by inhibiting sodium–proton exchange via cAMP-mediated D_{1A} receptors. This would account for previously unexplained

mucosal acidification during low-dose dopamine infusion. Direct effects of pharmacological agents on mucosal tissue must be taken into account when evaluating perfusion parameters based on tonometric data.

Visceral ischaemia is associated with systemic fibrinolysis in major aortic aneurysm surgery

P. Lintott, R. Stevens, H. Hafez, D. Hoppensteadt*, J. Fareed*, A. Mansfield, A. Nicolaides and G. Stansby, *Academic Surgical Unit, Imperial College at St Mary's, London, UK and *Thrombosis and Hemostasis Research Laboratories, Loyola University Medical Center, Illinois, USA*

Background Haemorrhagic problems are a common and potentially fatal complication following aneurysm surgery. The fibrinolytic system was investigated during elective thoracoabdominal aneurysm (TAA) and infrarenal aneurysm (AAA) surgery.

Methods Fifteen patients with TAA and 13 with AAA were studied. Tissue-type plasminogen activator (tPA) and plasminogen activator inhibitor 1 (PAI-1) antigen levels were measured in arterial plasma collected at incision, aortic clamping, immediately on reperfusion and 15, 60 and 180 min thereafter. Data are presented as median (interquartile range) and analysed using non-parametric tests (Wilcoxon or Mann–Whitney *U* test).

Results At incision patients with AAA had a higher baseline level of tPA than those with TAA ($P = 0{\cdot}003$). In both groups levels rose during the procedure and were always significantly higher than the initial value ($P < 0{\cdot}01$ at all time points). However, the rise on reperfusion was approximately three times greater in patients with TAA (36·4 (14·8–69·3) ng ml^{-1}) than in those with AAA (10·6 (7·6–11·9) ng ml^{-1}) ($P = 0{\cdot}002$). By 60 min after reperfusion, values were similar in both groups. Baseline PAI-1 levels were also similar in both groups. PAI-1 concentration showed a progressive and significant rise above baseline in both groups at all time points ($P < 0{\cdot}005$); however, there were no significant differences between the two groups at these times.

Conclusion tPA and PAI-1 activity is significantly increased in aneurysm surgery. Prophylactic administration of antifibrinolytic agents may be useful, especially when supracoeliac clamping is required.

Novel technique of perioperative leucodepletion: effect on cell counts and neutrophil activation

S. P. Cavanagh, A. Rawstron, M. J. Gough and S. Homer-Vanniasinkam, *Vascular Surgical Unit, The General Infirmary at Leeds, Leeds, UK*

Background Polymorphonuclear neutrophils (PMNs) are integral to the pathogenesis of ischaemia–reperfusion injury (IRI) and PMN depletion by both mechanical and immunological methods has been shown to ameliorate this injury in animal models. However, a clinical assessment of such techniques has not been performed.

Methods In ten patients undergoing limb salvage surgery the effect of PMN depletion (using a double-lumen femoral venous catheter, extracorporeal circuit, leucocyte filter, and flow rates of 200 ml min^{-1} for 15 min (3000 ml or approximately 60 per cent blood volume filtered)) on PMN, monocyte and lymphocyte counts, adhesion molecule expression (CD11b, CD18, L-selectin) and myeloperoxidase (MPO) levels was compared with changes in ten control patients undergoing similar surgery. Samples were taken from both peripheral (PER) and femoral (FEM) venous blood at baseline and at reperfusion, 4 h, 24 h, 3 and 6 days (T_0, T_4, T_{24}, T_{3D} and T_{6D} respectively).

Results PMNs were effectively depleted from the filtered blood from a median (interquartile range) of 4·04 (2·55–5·75) to 0·72 (0·42–1·30) $\times 10^9$ l^{-1} ($P = 0{\cdot}002$) and 1·08 (0·10–1·89) $\times 10^9$ l^{-1} ($P = 0{\cdot}012$) following 5 and 15 min of filtration respectively. Monocyte counts also fell from 0·30 (0·20–0·46) to 0·03 (0–0·20) $\times 10^9$ l^{-1} ($P = 0{\cdot}004$) at 5 min and 0·8 (0·03–0·10) $\times 10^9$ l^{-1} ($P = 0{\cdot}09$) at 15 min. Similar lymphocyte counts were reduced from 1·45 (1·09–1·9) to 0·1 (0·08–0·22) $\times 10^9$ l^{-1} at 5 min and 0·95 (0·58–1·3) $\times 10^9$ l^{-1} at 15 min ($P < 0{\cdot}0001$ at both points). PMN adhesion molecule expression was always lower in filtered patients (both FEM and PER), and was significant for CD11b at T_0 FEM ($P < 0{\cdot}0001$), T_4 PER ($P = 0{\cdot}0195$), T_{24} FEM ($P = 0{\cdot}0012$) and T_{3D} ($P = 0{\cdot}0140$). The reduction in CD18 expression was significant at T_0 PER ($P < 0{\cdot}0001$) and T_{24} FEM ($P = 0{\cdot}0311$), and falls in L-selectin were significant at T_4 PER ($P = 0{\cdot}0072$). Levels of MPO were higher in the filter group at T_0 FEM ($P < 0{\cdot}0001$) and T_4 FEM ($P < 0{\cdot}0001$).

Conclusion This novel study of intraoperative PMN depletion shows a favourable level of diminished activated neutrophils, which may ameliorate IRI. The incidence of infective complications, amputation and death was comparable between the two groups. It has thus been demonstrated that in patients undergoing limb revascularization this technique is safe, and the results suggest that further investigation is warranted.

Postural effect on lower limb arterial blood flow: a diagnostic marker of clinical severity in peripheral vascular disease

K. Delis, K. Otah, V. Ibegbuna, H. Hafez, G. Geroulakos, A. Lennox and A. Nicolaides, *Academic Surgical Unit, Imperial College School of Medicine, St Mary's Hospital, London, UK*

Background Lower limb arterial blood flow in normal subjects decreases as posture is altered from the horizontal to sitting position. This change, known as the venoarteriolar response (VAR), is due to local sympathetic axon reflex. Elevation of the lower limb venous pressure on dependency above a threshold level (pVAR) elicits the VAR, causing precapillary sphincters to contract and peripheral resistance to increase. The aim of the study was to determine whether the VAR and the pVAR are affected by peripheral vascular disease (PVD) in patients with intermittent claudication (IC) and whether they can be used as clinical markers for grading its severity.

Methods Eighty legs of normal volunteers (group 1) and 80 legs of patients with IC due to PVD (group 2) were included in the study. Two groups were matched for age and sex. Exclusion criteria were chronic cardiac failure, diabetes mellitus with peripheral neuropathy, chronic venous disease, leg oedema, collagen disease affecting the skin and use of nifedipine, all known to affect the VAR. Investigation entailed measurement of (1) maximal systolic ankle pressure (P_{ankle}), (2) resting (rABPI) and postexercise (peABPI) ankle:brachial pressure indices, (3) initial (pain free) (ICD) and absolute (ACD) claudication distances (treadmill 3·8 km h^{-1}, 10 per cent inclination) and (4) horizontal (HF) and sitting (SF) skin flow and the VAR (HF − SF/HF) obtained with laser Doppler fluxmetry on the dorsum of the foot. The ABPIs, P_{ankle}, VAR and pVAR were correlated with the ICD and ACD using linear regression.

Results

	VAR	pVAR (mmHg)	ICD (m)	ACD (m)	P_{ankle} (mmHg)
Group 1	0·59	45	—	—	145
Group 2	0·40	32	155	248	100
P*	< 0·05	< 0·05	—	—	< 0·05

Values are median. *Mann–Whitney *U* test

	Correlation coefficient				
	rABPI	peABPI	P_{ankle}	VAR	pVAR
ICD	0·36	0·33	0·2	0·62*	0·6*
ACD	0·39	0·33	0·23	0·65*	0·6*

$^*P<0{\cdot}02$

Conclusion The VAR and the venous pressure threshold that elicits it (pVAR) are significantly lower in claudicants than in normal subjects. The VAR and pVAR correlate significantly with the clinical severity of PVD, as determined by the ICD and ACD, yielding better correlation coefficients than the current clinical 'gold standard' of ABPI.

Aortic stent-graft incorporation and the inflammatory response to an endoprosthesis

A. W. Lambert, J. S. Budd, A. D. Fox, D. J. Williams, U. Potter, N. Rooney and M. Horrocks, *University Department of Surgery, Royal United Hospital, Bath, UK*

Background The incorporation of an endovascular stent-graft into the aorta of a pig was assessed and the inflammatory response to the endoprosthesis determined.

Methods Endoluminal stent-grafts were deployed into the infrarenal aortas of Large White pigs in accordance with Home Office Project Licence 30/01047. Animals were followed at intervals of up to 1 year. The aortas were explanted and specimens were subjected to gross observation, scanning electron microscopy (SEM) and light microscopy (LM).

Results Twenty-seven animals underwent infrarenal endoluminal stent-grafting. Four animals were excluded from follow-up because they had to be destroyed prematurely (aortic–stent-graft mismatch, acute stent-graft occlusion, iliac artery thrombosis, ear infection). The remainder were followed at 1 ($n=2$), 2 ($n=2$), 4 ($n=7$), 6 ($n=2$), 12 ($n=6$), 26 ($n=3$) and 52 ($n=1$) weeks. Macroscopically, an early neointima could be seen from week 4 and was well developed by week 12. SEM demonstrated intragraft thrombus at 1 week, with the development of a fibrin layer and islands of endothelial cells by week 2. A complete endothelial layer was seen at week 4. LM demonstrated a florid inflammatory reaction at 4 weeks, with lymphocytes and giant cells surrounding the graft. By 12 weeks the inflammation was marked by the presence of germinal centres. This response had largely subsided by 26 weeks and at 1 year only giant cells and a few lymphocytes persisted.

Conclusion In a porcine model, the aortic–stent-graft interface is well established by 4 weeks and complete by 12 weeks, by which time the stent-graft has a complete neointima. The initial acute inflammatory reaction seen at 4 weeks has become chronic by 12 weeks and is largely absent by 26 weeks after implantation.

Fast contrast-enhanced magnetic resonance angiography as a replacement for conventional digital subtraction angiography

A. Mohamed, J. Meaney, I. Robertson, S. Homer-Vanniasinkam and M. J. Gough, *Departments of Vascular Surgery and Radiology, Leeds General Infirmary and St James's University Hospital, Leeds, UK*

Background Digital subtraction angiography (DSA) is an invasive procedure with small but finite risks (vascular trauma, contrast reaction, radiation). Magnetic resonance angiography (MRA) avoids these problems although standard time-of-flight imaging is slow and may not differentiate between tight stenoses and occlusions. Thus a novel technique of MRA (gadolinium-enhanced contrast imaging: MRA-G) and a 'floating' table, as used for angiography, has been developed.

Methods Twenty patients (ten with intermittent claudication, ten with critical ischaemia; 14 men) underwent DSA and MRA-G. Gadolinium (40 ml, $0{\cdot}1\ \mathrm{mmol\ l^{-1}}$) was delivered via a peripheral vein over 2 min and scanning performed on a state of the art 1·5-T magnet. MRA images were acquired in 90 s over the abdomen/pelvis, thighs and legs (30 s each) providing images from the diaphragm to the foot. Reformatting allowed multiplanar views of all segments after a single contrast injection and scan.

Results All MRA-G studies were technically successful. Both the MRA-G and DSA films were assessed by two radiologists and two vascular surgeons. All occlusions or stenoses demonstrated by DSA were apparent on MRA-G. Furthermore, patent crural vessels were detected by MRA-G in four patients when not evident on DSA. In all patients the therapeutic decision based on MRA-G was identical to that for DSA.

Conclusion This study suggests that MRA-G may have a primary role for the rapid, non-invasive evaluation of patients with peripheral vascular disease. It provides images of comparable quality to DSA but with additional advantages of multiplanar views in all segments, routine demonstration of the whole of the intra-abdominal aorta and its branches, and enhanced imaging of crural vessels.

Identification of the unstable carotid plaque

T. J. Tegos, T. S. El-Atrozy, M. Sabetai, E. Kalodiki, S. Danjil, K. Kalomiris, D. Thomas and A. N. Nicolaides, *Irvine Laboratory, Academic Surgical Unit, Vascular Department, Imperial College School of Medicine, St Mary's Hospital, London, UK*

Background The aim of this study was to determine the relationship between ultrasonographically evaluated carotid plaque homogeneity (HOM) and the degree of carotid stenosis on duplex imaging with the incidence of ipsilateral cerebral infarction on computed tomography (CT) and cerebrovascular symptoms.

Methods A total of 150 consecutive patients with 192 plaques, 81 symptomatic and 111 asymptomatic, having 50–99 per cent carotid stenosis, were studied. Patients with cardioembolic symptoms were excluded. All ultrasonographic images of plaques were standardized in a computer so that the grey-scale median of blood was 0–5 and that of adventitia 180–200 on a linear scale from 0 to 255 (interobserver variability, $r=0{\cdot}93$). Homogeneity, a measure of the variability of tone in the neighbouring pixels, was evaluated with the spatial grey level dependence matrix method. The stenosis was evaluated on duplex imaging and the presence or absence of ipsilateral cerebrovascular symptomatology and CT infarction (discrete subcortical, large and small cortical which are probably thromboembolic) was noted.

Results A HOM of less than 0·3 and stenosis less than 70 per cent identified a group with an 11 per cent incidence of symptomatic plaques and a 16 per cent incidence of plaques associated with ipsilateral cerebral CT infarction. A HOM of less than 0·3 and stenosis equal to or greater than 70 per cent identified a group with incidences of 39 and 17 per cent respectively. A HOM equal to or greater than 0·3 and stenosis equal to or greater than 70 per cent identified a (high-risk) group with incidences of 59 and 37 per cent. A HOM equal to or greater than 0·3 and stenosis less than 70 per cent identified a group with incidences of 41 and 33 per cent respectively ($P<0{\cdot}05$, χ^2 test).

Conclusion These results indicate that computer-evaluated plaque homogeneity and degree of stenosis can identify plaques at high risk of cerebral CT infarction and symptoms, therefore having a potential application in the management and natural history studies of carotid plaques.

Influence of detection of silent cerebral infarction by magnetic resonance imaging on the management of carotid disease

A. J. McCleary, T. A. J. Calvey, M. Nelson, S. Homer-Vanniasinkam and M. J. Gough, *Departments of Vascular Surgery and Neuroradiology, The General Infirmary at Leeds, Leeds, UK*

Background Whilst carotid endarterectomy (CEA) is usually performed for symptoms matched by a greater than 70 per cent stenosis of the relevant artery, silent cerebral infarction (SCI) may also occur in association with carotid atherosclerosis and such patients might benefit from surgery. Similarly SCI detected after CEA has been suggested as one endpoint by which potential benefits of different surgical or anaesthetic techniques can be assessed.

Methods Magnetic resonance imaging (MRI) scans performed 24 h before and after CEA in 46 patients were examined by a neuroradiologist blinded to the clinical details in order to determine the prevalence of SCI both after operation and in association with moderate (30–69 per cent) and severe (more than 70 per cent) asymptomatic stenoses in the contralateral hemisphere.

Results Preoperative MRI demonstrated infarcts in 38 of 92 (41 (95 per cent confidence interval (c.i.) 31–51) per cent) hemispheres, 20 of which were associated with a previous cerebrovascular accident, seven with an apparent transient ischaemic attack and 11 with SCI for which there were no symptoms or signs (assessed by neurologist). In the SCI group seven infarcts occurred in 22 hemispheres ipsilateral to 30–69 per cent stenoses (32 (95 per cent c.i. 12–52) per cent), three in 13 hemispheres (23 (95 per cent c.i. 0–46) per cent) ipsilateral to more than 70 per cent stenoses and one with a less than 30 per cent stenosis. Only two new cerebral infarcts were evident after CEA, one in a patient with a previous hemiparesis who had no new signs and one following the onset of symptoms 30 min before surgery.

Conclusion Thus, despite a previous report, SCI following CEA is uncommon and as a consequence postoperative MRI will not increase the power of trials to detect an advantage between different surgical or anaesthetic techniques. In contrast MRI evidence of SCI in patients with both moderate and severe asymptomatic stenoses is common and could identify additional patients who might benefit from CEA.

Value of varicose vein surgery

J. J. Smith, A. M. Garratt, R. M. Greenhalgh and A. H. Davies, *Imperial College of Science, Technology and Medicine, Charing Cross Hospital, London, UK*

Background The incidence of varicose vein surgery in the population is high. Recently there has been a call to reduce surgery for this condition as it is often seen as cosmetic. This study assessed whether surgery for varicose veins significantly affects the patient's health-related quality of life (HRQL).

Methods The SF36 health questionnaire and Aberdeen Varicose Vein Questionnaire (AVVQ) (a previously validated specific measure of health outcome) were administered to 98 consecutive patients undergoing surgery for primary varicose veins. Patients were followed up 6 weeks after surgery (response rate 77 per cent) and repeated the questionnaires. Of the respondents there were 51 women (68 per cent) and the mean age was 47 years. Analysis was performed for reliability and responsiveness and changes in HRQL.

Results The reliability estimates (Cronbach's alpha) for the eight scales of the SF36 were all above 0·7 (range 0·74–0·87), and were 0·74 for the AVVQ. The mean preoperative scores for the eight scales of the SF36 were not significantly different from age- and sex-adjusted UK norms. The mean scores following surgery for six of the eight scales of the SF36 improved but not significantly ($P > 0{\cdot}4$, paired sample t test). The AVVQ scores improved significantly ($t = 4{\cdot}653$, $P < 0{\cdot}0001$). Standardized response mean for the AVVQ was 0·54 indicating that the AVVQ is able to detect clinically important changes in HRQL.

Conclusion Surgery for varicose veins leads to a significant increase in HRQL and use of the above instruments may help justify the use of scarce national health service resources.

Effect of angle and Miller cuff on impedance at end-to-side anastomoses

L. D. Wijesinghe, S. W. Smye and D. J. A. Scott, *St James's University Hospital, Leeds, UK*

Background Impedance is a measure of resistance in pulsatile circuits and may be used to describe the consequent flow disturbance associated with end-to-side anastomoses (ESAs). Changes in the geometry of ESAs are known to alter flow, distribution of shear forces and the dissipation of energy. The addition of a vein cuff is said to establish vortices that change the distribution of shear stress and favour an increase in patency. Since impedance is affected by ESA geometry, impedance analysis may be able to identify a haemodynamically ideal ESA. The effect of ESA geometries on impedance was investigated.

Methods ESAs were constructed from fixed lengths of polytetrafluoroethylene (inflow vessel 6 mm in diameter, outflow vessel 4 mm in diameter) in a standardized manner at various angles (15–120°) with and without a cuff (c). The ESAs were connected to a pulsatile pump delivering physiological flows (50–400 ml min^{-1}) and pressures (mean 50–100 mmHg). The pulse volume (P) and flow (Q) proximal to the ESA were measured with a pressure cuff and Doppler probe respectively, on a PVL-50 (SciMed, UK). The ratio P/Q was measured as a function of frequency to give an impedance index.

Results The values in the *Table* show impedance index (median of nine readings) at various flow rates. Repeatability was 0·05.

Flow (ml min^{-1})	15°	15°c	30°	30°c	45°	45°c	60°	60°c	90°	120°	120°c
100	0·85	0·71	1·02	0·95	1·20	1·09	1·36	1·21	1·49	1·75	1·71
200	1·10	0·93	1·32	1·25	1·49	1·38	1·63	1·50	1·79	2·15	1·95
300	1·17	0·95	1·43	1·33	1·55	1·50	1·72	1·61	1·80	2·24	1·96
400	1·20	1·02	1·42	1·34	1·57	1·51	1·72	1·62	1·81	2·18	1·99

$P < 0{\cdot}05$ at each flow rate (analysis of variance)

Conclusion At physiological flow rates, decreasing the angle of an ESA and/or constructing a Miller cuff reduces the impedance index of the anastomosis. This may explain the better patency rates observed in femoropopliteal grafts with a vein cuff.

Homocysteine induces endothelial cell dysfunction

A. M. Rasheed, J. H. Wang, C. Kelly, D. J. Bouchier-Hayes and A. Leahy, *Royal College of Surgeons in Ireland, Beaumont Hospital, Dublin, Ireland*

Background Despite recognition of homocysteine as an independent risk factor for atherogenesis, the mechanism of its atherogenicity remains unclear. This study assessed the effect of homocysteine on endothelial cell (EC) proliferation as a measure of its reparative capacity. EC function was also assessed by measuring nitric oxide and endothelin (ET-1), as both are indicators of atherogenicity.

Methods Human umbilical vein endothelial cells at passage 2–3 were treated with D,L-homocysteine (Sigma) at concentrations of 0, 0·01, 0·02, 0·05, 0·1, 1·0, 2·5 and 5 mmol l^{-1} for 24 h. EC proliferation was assessed using a 5-bromo-2′-deoxyuridine labelling and detection kit (Sigma). Nitric oxide production was measured using the Griess reaction after 24 and 48 h. ET-1 production was measured in the supernatant at 12, 24 and 48 h using a human ET-1 enzyme-linked immunosorbent assay kit (R and D).

Results

Homocysteine (mmol l^{-1})	Percentage decrease in proliferation	Nitric oxide production (μmol l^{-1}) 24 h	Nitric oxide production (μmol l^{-1}) 48 h	ET-1 production (mmol l^{-1}) 24 h	ET-1 production (mmol l^{-1}) 48 h
0	0	0·77	2·50	63	67
0·01	30	0·36	0·65	66	108
0·10	43	0·36	0·66	74	111
1·00	49	0·38	0·78	53	89
2·50	52	0·40	0·79	30	47
5·00	54	0·42	0·79	26	37
P*	< 0·02	< 0·03	< 0·05	< 0·02	< 0·02

*Analysis of variance

Conclusion Homocysteine inhibited EC proliferation, reduced nitric oxide concentration and upregulated ET-1 production. The increase in ET-1 concentration declined at around homocysteine 1 mmol l^{-1} suggesting EC toxicity. These data suggest an endothelium-dependent mechanism for the atherogenic effects of homocysteine.

Sympathetic skin response and patient satisfaction on long-term follow-up of thoracoscopic sympathectomy for hyperhidrosis

D. R. Lewis, F. C. T. Smith, P. M. Lamont and R. N. Baird, *Department of Surgery, Bristol Royal Infirmary, Bristol, UK*

Background Sympathetic skin response (SSR) is a measure of evoked endosomatic electrodermal activity. Patients with hyperhidrosis have abnormal SSRs which are abolished immediately following thoracoscopic sympathectomy. Absence of SSRs has been proposed as an objective measure of successful outcome following sympathectomy. A study was carried out to determine the effect of sympathectomy on SSR during long-term follow-up.
Methods Patients who had undergone bilateral thoracoscopic sympathectomy for hyperhidrosis underwent postoperative assessment of SSRs. A 15-mA stimulus was applied over the median nerve contralateral to the sympathectomy and evoked electrodermal activity was recorded from the sympathectomized palm. SSRs were analysed for amplitude. Patient satisfaction with surgery was assessed on a visual analogue scale (0–1·0).
Results Twenty-six patients were examined; 21 were female. Mean (range) age was 23 (9–36) years. Mean (range) follow-up was 39 (4–138) months. Twenty-four patients graded preoperative symptoms as severe. In three patients residual or recurrent symptoms occurred. Mean (range) patient satisfaction was 0·79 (0·06–1·0). In only seven of 52 palms were recurrent SSRs not detected.

SSRs	Amplitude (μV)
Mean (range)	714 (0–2906)
Normal	800–2000

Repeated-measures analysis of variance found no correlation between amplitude of SSR and time since surgery ($F = 0·48$, $P = 0·49$) or patient satisfaction.
Conclusion Following sympathectomy SSRs are not permanently abolished, but return of SSRs does not correspond with symptom recurrence or patient satisfaction. As such, SSRs are a poor tool for objective assessment of long-term outcome following sympathectomy.

Flow fields in *in vitro* end-to-side anastomoses: effect of disease progression and angle

L. D. Wijesinghe, S. W. Smye and D. J. A. Scott, *St James's University Hospital, Leeds, UK*

Background The addition of a distal vein cuff to a femorotibial polytetrafluoroethylene graft may improve patency but does not prevent the formation of intimal hyperplasia (IH). A flow vortex exists at the 'heel' of the cuff where shear stress is low and bloodborne factors which take part in thrombus formation or promote IH have an increased residence time. Little is known about the behaviour of this vortex with changing flow rate caused by disease progression.
Methods A flow circuit comprising a pulsatile pump was connected to polished glass models of standard or cuffed (height 1 or 2 cm end-to-side anastomoses (ESAs)) (inflow diameter 6 mm; outflow diameters 2 mm, angles 15, 30, 45, 60°). The proximal outflow channel was occluded 2 cm from the heel. The motion of illuminated particles was captured on video and analysed frame by frame to measure the maximum vortex height. Flow rate was altered by a clamp on the inflow or outflow tubing simulating progression of disease.
Results Values in the *Table* are vortex height in pixels (median of five measurements).

Flow (ml min^{-1})	Standard ESA 80	Standard ESA 100	Standard ESA 120	1-cm cuff 80	1-cm cuff 100	1-cm cuff 120	2-cm cuff 80	2-cm cuff 100	2-cm cuff 120
15°	44	41	42	77	77	79	121	119	122
30°	53	53	52	81	80	80	130	132	131
45°	68	66	69	95	96	96	150	148	151
60°	81	79	83	113	113	113	175	172	174

Conclusion Vortex height does not change with flow rate for a given cuff angle and ESA type, but increases with anastomotic angle ($P < 0·05$, analysis of variance) and cuff height. The development of IH may be favoured by a tall cuff (large vortex) whereas a long and low cuff (shallow angle ESA, small vortex) may be able better to accommodate any IH before it causes a significant flow reduction. Although the small vortex is in a shallow standard ESA, the ESA volume may not be large enough to compensate for any IH that develops.

Treatment of internal carotid artery thrombosis: an *in vitro* model

H. Chant, S. Fearn, D. McHugh, R. Ashleigh and C. N. McCollum, *Department of Surgery, South Manchester University Hospital, Manchester, UK*

Background This study compared the ability of commercially available thrombectomy catheters to clear thrombus from an *in vitro* model of complete internal carotid artery (ICA) thrombosis.
Methods A glass model of the ICA was filled with human blood which was allowed to coagulate. The Hydrolyser (Cordis, The Netherlands), Clot Buster (Microveena, USA), Acolysis System (Angiosonics, USA), Angiojet (Possis Medical, USA) and an Intimax Embolectomy Catheter (Applied Medical, USA) were each tested for pressure changes distal to catheter tip on activation and ability to clear the thrombus from the model.

Results

Catheter	n	Pressure change (mmHg)	Model clearance (%)*
Clot Buster	8	− 50	89·0 (71·5–95·8)
Hydrolyser	9	− 30	79·9 (53·2–93·0)
Balloon	5	< − 50 to > + 50	90·0 (86·9–94·8)
Acolysis	7	0	33·8 (11·8–49·8)
Angiojet	8	− 30 to + 100	94·7 (92·2–97·5)

*Values are median (range)

The Clot Buster produced the lowest tip pressure. Both the balloon catheter and the Angiojet created positive pressures distal to the tip with the potential for distal embolization. The clearance achieved by the Clot Buster and the Hydrolyser were not significantly different to that produced by the balloon catheter and the Angiojet (Kruskall–Wallis test). Furthermore, the Clot Buster and Hydrolyser are easier and cheaper to use.
Conclusion So far, the Clot Buster and the Hydrolyser show the greatest potential for use in carotid endarterectomy with complete ICA thrombosis.

Hypocoagulability and failure of compression ultrasonography for false aneurysm

D. R. Lewis, A. H. Davies*, R. N. Baird, P. M. Lamont and F. C. T. Smith, *Bristol Royal Infirmary, Bristol and *Charing Cross Hospital, London, UK*

Background False femoral artery aneurysm is an occasional complication of percutaneous cardiovascular radiological procedures. Compression ultrasonography causes thrombosis non-invasively, reducing need for operative intervention. The technique fails in a proportion of cases. Analysis was undertaken to identify causes of failure.
Methods Patients presenting with false femoral artery aneurysm since 1984 were identified from a computerized database (BIPAS). Since 1993 compression ultrasonography has been performed as first-line treatment according to a standard protocol. The aneurysm jet is located and compressed with the 5-MHz probe of an ATL Ultramark 9 colour flow duplex scanner. Up to three 10-min compressions are performed per treatment. Prospectively collected ultrasonographic data and case notes were reviewed to identify causes of failed compression.
Results False femoral artery aneurysm occurred as a complication in 27 (0·1 per cent) of 24 033 cardiovascular radiological procedures. Fifteen aneurysms were treated by compression. The technique was successful in nine of 15 cases but primary failure occurred in six. Five of six had abnormal clotting ($\chi^2 = 7{\cdot}17$, $P = 0{\cdot}005$); three were anticoagulated and compression was subsequently successful in two of these patients following reversal of warfarin therapy. In three of 15 cases surgical repair was necessary. Size of aneurysm, velocity of flow jet and size of endoluminal catheter were not found to be significant factors in failure of treatment.
Conclusion Compression ultrasonography is an effective treatment of false femoral aneurysm. Hypocoagulability reduced effectiveness. For patients in whom anticoagulation cannot be reversed, primary surgical repair should be considered.

Tetracycline modulates cytokine secretion in human abdominal aortic aneurysms

I. J. Franklin, L. J. Walton and J. T. Powell, *Department of Surgery, Charing Cross and Westminster Medical School, London, UK*

Background Paracrine interactions between inflammatory and collagen synthesizing cells appear to be important in the growth of abdominal aortic aneurysms. Interrupting these processes with drugs provides a potential method of limiting aneurysm expansion.
Methods Explant cultures of human aorta have been established and characterized to investigate collagen metabolism and cytokine production in the aneurysm wall. How collagen turnover (hydroxyproline secretion) and cytokine release (measured by enzyme-linked immunosorbent assay) are influenced by tetracycline is now reported.
Results Histological examination demonstrated preservation of explant tissue architecture for up to 6 days. The concentration of hydroxyproline released into the culture medium was unchanged in the presence of tetracycline at either 10 or $100\,\mu g\,ml^{-1}$. The explants secreted the cytokine monocyte chemotactic protein 1 (MCP-1) but not tumour necrosis factor α or interferon γ. The release of MCP-1 was reduced in the presence of tetracycline in a concentration-dependent manner.

Conditioned medium at 48 h	Control	Tetracycline ($\mu g\,ml^{-1}$)	
		10	100
Hydroxyproline ($\mu g\,ml^{-1}$) ($n = 9$)	31·4(7)	32·4(9)	29·4(5)
MCP-1 ($ng\,ml^{-1}$) ($n = 5$)	18·9(11·8)	16·5(6)	5·2(2·8)*

Values are mean(s.d.). *$P < 0{\cdot}01$

Conclusion Macrophages are the source of collagen-degrading enzymes in the aneurysm wall. The ability of tetracycline to inhibit secretion of MCP-1, the most potent attractant for macrophages, might translate clinically to reduced aneurysm expansion.

Antioxidant capacity in vascular patients in relation to nutrition or severity of ischaemia

I. Spark, J. Robinson, S. Homer-Vanniasinkam, M. J. Gough, R. C. Kester and D. J. Scott, *Departments of Vascular Surgery, Leeds General Infirmary and St James's University Hospital, Leeds, UK*

Background Previous work indicates that a reduced total antioxidant capacity (TAC) increases the risk of postoperative infection in patients undergoing femorodistal bypass. However, it is not known whether such a reduction is dependent upon the severity of ischaemia or the patient's nutritional status.
Methods The TAC and nutritional status of two groups of patients with differing severities of vascular disease (14 (nine men, median age 72 years) with critical limb ischaemia (rest pain, ankle pressure less than 50 mmHg); 13 claudicants (seven men, median age 68 years)) has been compared with that of ten controls (six men, median age 64 years). Nutritional status was assessed by mid-arm circumference, triceps skinfold thickness, body mass index, lean body mass, maximum voluntary contraction (hand grip dynamometer), bioelectrical impedance, and levels of serum albumin, prealbumin and transferrin. These markers were then correlated with TAC.
Results Patients with peripheral vascular disease had a lower median TAC than controls (752 *versus* $1130\,\mu mol\,l^{-1}$; $P < 0{\cdot}05$, Mann–Whitney U test) although there was no difference between claudicants and patients with critical ischaemia (789 *versus* $721\,\mu mol\,l^{-1}$). However, TAC did correlate with maximum voluntary contraction ($r_S = 0{\cdot}64$, $P = 0{\cdot}037$), lean body mass ($r_S = 0{\cdot}60$, $P = 0{\cdot}043$) and serum transferrin level ($r_S = 0{\cdot}67$, $P = 0{\cdot}02$).
Conclusion These results indicate that TAC is influenced by nutritional status rather than the severity of ischaemia. Thus the risk of postoperative sepsis might be reduced by preoperative augmentation of both antioxidant and nutritional status before either limb salvage surgery or operation for claudication.

Hyperhomocysteinaemia, peripheral vascular disease and neointimal hyperplasia in elderly patients

S. Caldwell, M. McCarthy, S. C. Martin*, A. C. Hilton*, W. A. Bartlett*, A. F. Jones* and D. A. Mosquera, *Departments of Surgery and *Clinical Chemistry, Birmingham Heartlands Hospital, Birmingham, UK*

Background Hyperhomocysteinaemia is a reported risk factor in patients with premature peripheral vascular disease (PVD) and in vein bypass grafts with neointimal hyperplasia (NIH). Its prevalence in a more typical group of vascular patients is unknown. The aims of this case-controlled study were to determine the prevalence of hyperhomocysteinaemia in unselected patients with PVD and in patients with NIH.
Methods Homocysteine was measured in fasting plasma from subjects and controls in a high-pressure liquid chromatography assay. Control results were logarithmically transformed for a reference range (mean plus two standard deviations) of 8·86–14·25 μmol l^{-1}.

	Controls ($n=30$)	PVD ($n=35$)	NIH ($n=15$)
Homocysteine (μmol l^{-1})	11·30 (9·37–14·07)	15·80 (11·10–19·50)*	12·00 (6·90–14·20)†

Values are median (interquartile range). *$P=0{\cdot}001$, †$P=0{\cdot}72$ *versus* controls (Mann–Whitney U test)

Results Hyperhomocysteinaemia (homocysteine greater than 14·25 μmol l^{-1}) was present in seven of 30 controls and 22 of 35 patients with PVD ($\chi^2=10{\cdot}212$, $P=0{\cdot}001$ *versus* controls) but in only three of five patients with NIH ($\chi^2=0{\cdot}064$, $P=0{\cdot}80$ *versus* controls). Serum folate concentrations in the patients with PVD were lower than those in patients with NIH: mean(s.e.m.) 4·5(0·3) *versus* 7·6(1·1) μmol l^{-1} respectively ($P=0{\cdot}015$, t test).
Conclusion Hyperhomocysteinaemia is strongly associated with PVD and this association appears even stronger than in patients with premature PVD. In contrast to a previous report there was no association with NIH and this may be attributable to differences in folate concentrations.

Cytokine response to perioperative leucodepletion during limb salvage surgery

S. P. Cavanagh, A. Rawstron, M. J. Gough and S. Homer-Vanniasinkam, *Vascular Surgical Unit, The General Infirmary at Leeds, Leeds, UK*

Background Polymorphonuclear neutrophils (PMNs) promote ischaemia–reperfusion (IRI), and PMN depletion by both mechanical and immunological methods has been shown to ameliorate this injury in animal models. However, thus far leucodepletion has not been subjected to clinical assessment.
Methods In ten patients undergoing limb salvage surgery the effect of PMN depletion (using a double-lumen femoral venous catheter, extracorporeal circuit, leucocyte filter, and flow rates of 200 ml min^{-1} for 15 min (3000 ml or approximately 60 per cent of blood volume filtered) on levels of interleukin (IL) 6, IL-8 and tumour necrosis factor (TNF) α were compared with the same measurements in ten control patients undergoing similar surgery. Samples were taken from both peripheral (PER) and femoral (FEM) venous blood at baseline, reperfusion (T_0), 4 h, 24 h, 3 and 6 days (T_4, T_{24}, T_{3D} and T_{6D}).
Results Except at baseline, levels of IL-6 were lower in the patients who had filtration at all time points. These differences (filtered *versus* control, expressed as median percentage change from baseline) were significant at T_0 FEM (+122 *versus* +148 per cent, $P<0{\cdot}0001$), T_0 PER (+15 *versus* +52 per cent, $P<0{\cdot}0001$), T_{3D} (+79 *versus* +444 per cent, $P=0{\cdot}025$) and T_{6D} (−24 *versus* +221 per cent, $P=0{\cdot}046$). TNF-α levels were higher in those who had leucodepletion, particularly at T_0 PER (−16 *versus* −17 per cent, $P<0{\cdot}0001$) and T_4 PER (−9 *versus* −43 per cent, $P<0{\cdot}0001$). Levels of IL-8 were lower in the PER samples (T_0 +1·8 *versus* +4·1 per cent, $P<0{\cdot}0001$; T_{24} +2 *versus* +125 per cent, $P<0{\cdot}0001$) but higher in FEM samples (T_4 +24 *versus* +5 per cent, $P<0{\cdot}0001$; T_{24} +72 *versus* +49 per cent, $P<0{\cdot}0001$) of patients who had filtration.
Conclusion This novel study of intraoperative PMN depletion is associated with changes in the cytokine profile that would be consistent with amelioration of IRI. Thus levels of the PMN-dependent proinflammatory cytokine IL-6 were reduced, whilst those of IL-8 in femoral blood increased (leucocyte adhesion inhibition effect). Similarly peripheral TNF-α levels were higher and this should suppress PMN release from bone marrow reserves. The incidence of infective complications, amputations and death was comparable in the two groups. This technique appears safe, and its therapeutic role warrants further investigation.

Upregulation of mesothelial heparin-binding epidermal growth factor by peritoneal cytokines: implications for tumour metastases

D. G. Jayne, S. Perry, S. Farmery, A. C. J. Windsor, N. S. Ambrose and P. J. Guillou, *Professorial Surgical Unit, St James's University Hospital, Leeds, UK*

Background Heparin-binding epidermal growth factor (HB-EGF) is a newly characterized growth factor which is mitogenic for EGF receptor-positive tumour cells and shares similar heparin-binding properties to basic fibroblast growth factor (bFGF). It is upregulated in endothelial cells by the cytokines tumour necrosis factor (TNF) α and interleukin (IL) 1β which are abundant in the peritoneal cavity after operation. The aim of the present study was to determine their effect on human mesothelial expression of HB-EGF and bFGF.
Methods Samples of human omentum (ethics committee approved) were enzymatically digested and used to establish mesothelial cell cultures. Confluent cells were stimulated with commercial TNF-α and IL-1β or postoperative drain exudate and subjected to semiquantitative reverse transcription–polymerase chain reaction using gene-specific primers for HB-EGF, bFGF and the house-keeper gene glyceraldehyde-3-phosphate dehydrogenase.
Results Mesothelial cells showed a low constitutive expression of HB-EGF and bFGF messenger RNA. TNF-α and IL-1β significantly stimulated HB-EGF expression in a dose- and time-dependent manner, maximally at 1 ng ml^{-1} and 4 h; bFGF expression was unchanged. In the *Table*, results for a 4-h incubation are expressed as a ratio of growth factor : glyceraldehyde-3-phosphate dehydrogenase amplified products normalized for controls (no stimulation).

	HB-EGF	bFGF
TNF-α (1 ng ml^{-1}) ($n=6$)	3·2 (2·9–3·9)*	1·1 (0·9–1·2)
IL-1β (1 ng ml^{-1}) ($n=6$)	2·7 (1·5–3·2)*	1·0 (0·7–1·2)

Values are median (interquartile range). *$P=0{\cdot}03$ (Wilcoxon signed rank test)

A similar increase in HB-EGF expression occurred following incubation with drain exudate, and was attenuated by pretreatment with anti-IL-1 and anti-TNF antibodies.
Conclusion The cytokine environment of the postoperative peritoneal cavity results in the production by human mesothelial cells of a growth factor (HB-EGF), which is known to be mitogenic for gastrointestinal cancer. These findings have profound implications for the aetiology and prevention of local tumour recurrence.

Drug resistance evaluation by functional assay and immunofluorescence in bladder cancer

I. Yu-Shing Chong, V. Bradley, C. Davies, M. Hayes*, M. Loizidou, A. J. Cooper* and I. Taylor, *Department of Surgery, University College London Medical School, London and *Department of Urology, Southampton General Hospital, Southampton, UK*

Background Superficial bladder cancer frequently recurs and can evoke repeated chemotherapy. However, multidrug resistance (MDR) limits the effectiveness of chemotherapy.
Methods MDR was assessed in recurrent bladder cancer ($n = 11$) by: (1) immunofluorescent staining of three proteins associated with MDR, P-glycoprotein (P170), MDR-related protein (MRP) and lung resistance protein (LRP) in frozen sections; and (2) confocal microscopy of epirubicin accumulation ($20\,\mathrm{mg\,ml^{-1}}$, 2 h) in primary explants in culture. Specifically, intracellular drug distribution was determined including changes under the influence of the MDR reversing agents, verapamil and PSC833. Five cell lines (including resistant variants) were used for method development and afforded the 'gold standard' results for both assays.
Results Seven of 11 specimens exhibited positive immunofluorescence: five for P170 with or without other MDR proteins, one for MRP and one for LRP, with the percentage of stained cells usually below 15 per cent. Of the seven immunohistochemically resistant cancers, only five showed a resistant pattern of epirubicin uptake in culture, i.e. less total drug uptake compared with sensitive cultures (three to ten times), nuclear exclusion of drug, reversal of the latter pattern using verapamil and/or PSC833. Of the four specimens with negative immunofluorescence, two grew explants that were resistant *in vitro*. Overall, only seven of 11 specimens gave matching results using both assays (sensitive/sensitive or resistant/resistant).
Conclusion These early results show that both immunofluorescence and functional assays give information on MDR status. The majority of tumours showed at least small populations of resistant cells. The clinical implication is that reversal strategy should be developed for early or prophylactic implementation.

Colorectal tumours are highly heterogeneous in chromosome number at the single cell level

J. Greenman, J. Ashman, V. Brankin, G. S. Duthie, P. W. R. Lee, M. J. Kerin and J. R. T. Monson, *Academic Surgical Unit, University of Hull, Hull, UK*

Background The multistep hypothesis for colorectal carcinogenesis proposed by Vogelstein involves genes located on a number of chromosomes. In particular, chromosomes 7, 17 and 18 have been reported to carry critical genes. In this study a three-colour fluorescence *in situ* hybridization (FISH) approach was used to investigate the number of these three chromosomes within individual tumour cells to determine tumour heterogeneity. The FISH data were also correlated with the gross ploidy index of the tumour.
Methods Tumour biopsies ($n = 50$) were taken from a non-necrotic region of tumour and touch-preparations were made on to Vectabond-treated microscope slides. These slides were used in FISH experiments with three pericentromeric chromosome probes: chromosome 7 was detected with fluorescein isothiocyanate (FITC), chromosome 17 with Texas Red, and chromosome 18 with a mixture of FITC- and Texas Red-labelled probes. One slide was Feulgen stained for quantitative image analysis using a CAS image analyser.
Results FISH analysis showed a high level of heterogeneity in the vast majority of samples. The most frequently occurring modal chromosome profile was 2/2/2 (41 per cent) for chromosomes 7, 17 and 18 respectively, although the ploidy index of these tumours varied from 0·93 to 2·06 with no correlation to histological stage. A modal profile of (3/4)/2/2 was the most commonly found profile in Dukes B (eight of 19) and C (six of 16) tumours but again no correlation with DNA ploidy was observed.
Conclusion This study shows that tumours are highly heterogeneous at the single cell level and that a modal chromosome profile does not correlate directly with total DNA ploidy or histology of a tumour. It is hypothesized that tumour outcome may be better predicted by the presence of particular subpopulations of cells found within a tumour mass rather than by total DNA ploidy.

Suicide gene therapy for colorectal liver metastases: evidence of a systemic antitumour immune response

I. M. Pope, F. Campbell*, J. Yates, G. Lepts, G. Mellor*, R. B. Jones†, S. E. Christmas†, A. R. Kinsella and G. J. Poston, *University Departments of Surgery, *Pathology and †Immunology, Royal Liverpool University Hospital, Liverpool, UK*

Background Expression of the herpes simplex virus type 1 thymidine kinase (HSV1-TK) gene in localized tumours results in tumour regression following the administration of ganciclovir (GCV). A localized immune response contributes to this regression. The aim of this study was to determine if the treatment of localized HSV1-TK-expressing colorectal liver metastases resulted in a systemic antitumour immune response and the regression of distant metastases. The effect of HSV1-TK expression in the absence of drug selection was also investigated.
Methods Liver metastases were generated by the subcapsular injection of 5×10^6 cells of the K12TK cell line (groups 1 and 2) and K12 cell line (group 3) in BDIX rats. All animals received a second injection of the K12 cell line in an adjacent lobe of the liver. After 7 days, group 2 was treated with intraperitoneal GCV $75\,\mathrm{mg\,kg^{-1}}$ twice daily for 5 days. Animals were killed, tumour volumes were determined and T cell cytotoxicity assays performed. Experiments were performed under the Animals (Scientific Procedures) Act 1986.
Results HSV1-TK-expressing tumours showed marked regression following GCV (group 2): mean tumour volume $0{\cdot}6\,\mathrm{mm}^3$ compared with $98{\cdot}4\,\mathrm{mm}^3$ for controls (group 3) ($P < 0{\cdot}0001$, Mann–Whitney U test). However, HSV1-TK protein expression alone also resulted in tumour regression (group 1): mean tumour volume $22{\cdot}4\,\mathrm{mm}^3$ ($P < 0{\cdot}05$). Adjacent tumours in group 2 had a mean tumour volume of $45{\cdot}2\,\mathrm{mm}^3$ (P not significant), whilst those in group 1 showed significant regression: mean tumour volume $20{\cdot}2\,\mathrm{mm}^3$ ($P < 0{\cdot}05$). A cytotoxic T cell population recognizing the unmodified K12 cell line was identified in group 2.
Conclusion HSV1-TK-mediated therapy of experimental liver metastases results in a systemic antitumour immune response. The TK protein appears to have a role in the generation of antitumour immunity.

Frequent G to T transversion at codon 249 of the *p53* tumour suppressor gene in hepatocellular carcinoma

P. B. S. Lai, S. M. Ip, W. Y. Lau and A. K. C. Li, *Department of Surgery, The Chinese University of Hong Kong, Prince of Wales Hospital, Shatin, New Territories, Hong Kong*

Background Hepatocellular carcinoma (HCC), a common malignancy in south-east Asia, accounts for over 1 000 000 deaths per year worldwide. In Hong Kong, HCC is the second leading cause of cancer death. Both exposure to dietary carcinogens such as aflatoxin B_1 and infection of hepatitis B virus have been implicated as important risk factors for the development of HCC. The genetic mutation of the *p53* gene in HCC was studied.
Methods DNA extracted from 52 operative tumour samples of HCC was used. Point mutations were detected by single-stranded conformational polymorphism and direct DNA sequencing techniques.
Results Within exons 5–8 of the *p53* gene, 17 point mutations were detected in the 52 samples. The frequencies of point muta-

tion in exons 5, 6, 7 and 8 were four of 17, three of 17, nine of 17 and one of 17 respectively. Furthermore, eight of the nine point mutations in exon 7 were found to be G to T transversion at codon 249.
Conclusion These findings suggest that G to T transversion at codon 249 of the *p53* tumour suppressor gene was a common genetic alteration in this series. As such transversion is commonly found in HCC because of dietary exposure to aflatoxin B_1, this may represent a subset of HCC in Hong Kong.

Desmoid precursor lesions

S. K. Clark, T. G. P. Johnson-Smith, D. E. Katz, R. H. Reznek*, I. M. Frayling and R. K. S. Phillips, *The Polyposis Registry and Department of Radiology, Northwick Park and St Mark's Hospital, Harrow and *Department of Radiology, St Bartholomew's Hospital, London, UK*

Background Germline mutations of the *APC* tumour suppressor gene on chromosome 5q22 are responsible for familial adenomatous polyposis (FAP). Desmoid tumours are poorly understood, locally invasive, non-metastasizing neoplasms that occur in about 10 per cent of patients with FAP. The natural history of desmoids was investigated by documenting prospectively the prevalence and progression of possible precursor lesions, and comparing the somatic genetics of these with established desmoid tumours.
Methods A group of patients with FAP and controls were examined at laparotomy. Another group, with FAP and no clinical evidence of desmoid, and a group of controls underwent helical abdominopelvic computed tomography. DNA from 17 desmoids (from 13 patients with FAP) and from eight putative precursor lesions biopsied at laparotomy was assessed for allele loss at five dinucleotide repeat microsatellite markers flanking *APC*. Mutations in *APC* exon 15 were detected using heteroduplex analysis of overlapping polymerase chain reaction products and the protein truncation test. Regions found to contain mutations were directly sequenced.
Results At laparotomy, 13 of 42 patients with FAP had fibromatous mesenteric plaques; seven had no history of surgery. Seven had more extensive mesenteric fibromatosis; these individuals had undergone significantly more laparotomies than the rest. Of 103 patients scanned, two had desmoid tumours and 22 (21 per cent) had mesenteric fibromatosis. On follow-up both desmoid tumours grew rapidly; mesenteric fibromatosis was unchanged in five and resolved in four of the nine patients rescanned. Somatic mutation was identified in 11 of 17 desmoids and allele loss at *APC* in two. No somatic abnormalities of *APC* were detected in the putative precursors ($P<0\cdot05$, Fisher's exact test), all of which were histologically compatible with desmoid.
Conclusion A model of desmoid tumour development, analogous to the adenoma–carcinoma sequence, is proposed, in which a less benign phenotype emerges as molecular genetic abnormalities accumulate. Mesenteric plaque-like desmoid precursor lesions arise before surgery in many patients with FAP as a result of abnormal fibroblast function; some, perhaps stimulated by surgery, progress to mesenteric fibromatosis; these in turn can give rise to a desmoid tumour.

Nucleotide excision–repair of damaged DNA is inhibited by doxorubicin in human tumour cells

C. Whitaker, A. Sattar, A. Harbottle and F. C. Campbell, *Department of Surgery, University of Newcastle, Newcastle-upon-Tyne, UK*

Background Nucleotide excision–repair (NER) removes DNA damage induced by ultraviolet (UV) radiation or by cisplatin and may affect tumour chemosensitivity. This study assayed NER in human adenocarcinoma cells and assessed effects of doxorubicin on this process.
Methods NER was assessed by tumour cell reactivation of UV-damaged DNA of the chloramphenicol acetyltransferase (CAT) reporter gene. DNA damage impairs CAT activity. Any subsequent increase of activity indicates NER and provides a quantitative assay. UV-damaged and normal CAT genes were incorporated into recombinant adenoviral vectors (UV Ad-CAT and Ad-CAT respectively) which were used to infect cells. CAT activity was assessed by radioligand binding assay. Effects of doxorubicin were then assayed.
Results High levels of CAT activity were induced by infection with undamaged Ad-CAT (mean(s.d.) 30(3) to 45(8) *versus* 5(2) c.p.m. in control). CAT activity levels were initially low (8(2) c.p.m. on day 1) after infection by UV Ad-CAT, but subsequently increased to 18(2) c.p.m. by day 4, indicating effective NER. Doxorubicin inhibited NER in cells infected with UV AD-CAT, and CAT activity remained low (8(2) c.p.m. on day 4).
Conclusion Human adenocarcinoma cells have high NER activity which could impair responsiveness to cisplatin. Doxorubicin inhibits NER and may enhance chemosensitivity.

Correlation of a colour subtraction pulse sequence for magnetic resonance-guided interstitial thermoablation with temperature and histological lesion size

S. Gould, G. Lamb, N. Vaughan, W. Gedroyc, A. Mansfield and A. Darzi, *Academic Surgical Unit, Imperial College of Medicine at St Mary's and Centre for Biological and Medical Systems, Imperial College, London, UK*

Background Magnetic resonance (MR) imaging is the most sensitive modality for monitoring interstitial laser thermotherapy (ILT). However, dependence on interpretation of grey-scale changes and variable tissue T1 times make it less than ideal. A prototype real-time pulse sequence (General Electric (GE), USA) that assigns a colour spectrum to grey-scale changes will potentially increase the accuracy of MR-guided thermal surgery. However, the spectrum must be calibrated with temperature and image-predicted necrosis correlated with histological effect to allow its clinical use.
Methods Porcine livers were placed within a 0·5-T GE SP10 Interventional MR Unit. A 600-μm neodymium yttrium–aluminium–garnet laser fibre (wavelength 1064 nm) with diffuser tip was placed in the liver parenchyma with an MR-compatible thermocouple. A sagittal MR image containing the fibre tip was chosen as the template. A 3-cm region of interest (ROI) was drawn centred on the fibre. Thermal lesions were produced (5 W, duration 20 min) with real-time colour subtraction MR monitoring throughout (FGR60, acquisition time 4 s). At 1-min intervals the pixel intensity value, temperature and colour at the laser tip were measured. Twenty burns were produced. The pixel intensity measurements were expressed as a percentage of the mean pixel intensity of the ROI to standardize measurements. Using the colour representing the temperature at which tissue necrosis would be expected to occur, predicted maximum lesion size was measured from the images and compared with histological assessment.
Results There was a linear relationship between temperature and percentage pixel change ($r=0\cdot84$). Six discrete colours were determined in the spectrum and all were significantly different from each other in terms of mean percentage pixel change ($P<0\cdot01$) and mean temperature ($P<0\cdot01$; except between orange and yellow, $P=0\cdot037$). Green had a mean(s.d.) temperature of 55·6(5)°C, and thus predicted necrosis. Image-predicted maximum lesion size correlated closely with histology ($r=0\cdot93$).
Conclusion The colour changes produced by this unique pulse sequence have been calibrated with tissue temperature *in vitro*. The colour representing a temperature above which necrosis is known to occur can be used accurately to predict lesion size. This will potentially allow greater accuracy and safety for MR monitoring of ILT *in vivo*.

Genomic heterogeneity in synchronous hepatocellular cancers

Y. Sirivatanauksorn*‡, V. Sirivatanauksorn§, S. Bhattacharya*, J. Rees†, A. K. Savage†, A. P. Dhillon‡, A. K. Kakkar‡, N. R. Lemoine§, R. C. N. Williamson‡ and B. R. Davidson*, *Departments of *Surgery and †Histopathology, Royal Free Hospital School of Medicine, and ‡Department of Surgery and §Imperial Cancer Research Fund Oncology Unit, Hammersmith Hospital, Imperial College School of Medicine, London, UK*

Background Hepatocellular carcinoma (HCC) arising in a cirrhotic liver is frequently multifocal. Whether the smaller lesions represent intrahepatic metastases or *de novo* cancers has not been established. Their degree of genomic heterogeneity was assessed using arbitrarily primed polymerase chain reaction, a new but well validated technique of DNA fingerprinting not requiring prior sequence information.
Methods Sixty nodules (37 HCC, 23 regenerative nodules) were sampled from ten human cirrhotic livers removed at orthotopic liver transplantation. Tumour tissue was microdissected from paraffin-embedded formalin-fixed samples, and phenol extraction of genomic DNA was performed. Two arbitrary primers (AR3 and ZF3) were used to amplify the genomic DNA of each sample. Fingerprinting of the random amplified fragments was performed by acrylamide gel electrophoresis.
Results Marked genomic heterogeneity was noted amongst the nodules studied. No two cancers or regenerative nodules had identical electrophoretic patterns. Even HCCs in close proximity and within the same segment of the liver were found to have distinct genomic patterns.
Conclusion Such genomic heterogeneity in synchronous HCCs may explain the poor response to treatment of these cancers. Also, if the smaller tumours are *de novo* lesions rather than metastases, as these data suggest, then current concepts regarding liver resection as a curative treatment modality for HCC may require reassessment.

Protective role of the current preservation solutions against warm ischaemia in rat kidney

N. Ahmad, D. J. Potts* and J. P. A. Lodge, *Department of Organ Transplantation, St James's University Hospital and *Department of Physiology, University of Leeds, Leeds, UK*

Background The protective role of current preservation solutions in the prevention of warm ischaemic and reperfusion injury in a rat kidney model is reported. The solutions studied included Euro-Collins (EC), hyperosmolar citrate (HOC), phosphate-buffered sucrose (PBS140) and University of Wisconsin solution (UW).
Methods Male Wistar rats (300–350 g) were anaesthetized by intraperitoneal injection of inactin 120 mg kg^{-1}. An intravenous infusion was set up at 6 ml h^{-1} (sodium chloride 125 mmol l^{-1}, bicarbonate 25 mmol l^{-1}) also containing 37 MBq l^{-1} [^{3}H]inulin (for inulin clearance). Both ureters were cannulated for serial urine collection. An equilibration period of 1 h was allowed following surgery after which urine was collected for 1 h (control). The left kidney was then flushed with 0·5 ml 0·9 per cent saline, EC, HOC, PBS140 or UW at 37°C. A clamp was then applied to the left renal pedicle. After 45 min the clamp was released and a right nephrectomy was performed. Urine flow and composition from the left kidney were observed for 4 h. Home Office guidelines were strictly followed in all animal experiments.
Results Results are presented for inulin clearance, urine flow and urine osmolality in the third hour after ischaemia compared with preischaemic control values.

Function	Period	Saline	EC	HOC	PBS140	UW
GFR (μl min^{-1})	Before ischaemia	611(64)	839(146)	604(92)	721(96)	1125(128)
	After ischaemia	31(14)	146(108)	168(102)	365(87)	534(162)
Urine flow (μl h^{-1})	Before ischaemia	428(37)	530(154)	575(224)	468(76)	413(76)
	After ischaemia	607(282)	848(456)	1280(576)	1566(565)	1873(521)
Osmolality (mosm l^{-1})	Before ischaemia	1087(53)	1016(167)	1050(236)	1024(98)	1094(127)
	After ischaemia	331(8)	366(28)	436(28)	499(37)	519(45)

Values are mean(s.e.m.) ($n = 6$). GFR, glomerular filtration rate

Conclusion Forty-five minutes of warm ischaemia to rat kidney was considered very severe. Both PBS140 and UW provided effective protection resulting in high output of concentrated urine compared with EC and HOC.

Matrix metalloproteinases and angiogenesis in breast cell line co-cultures with fibroblasts

R. A. Cochrane, E. L. Davies, M. K. Roy, P. D. Carey and R. E. Mansel, *University Department of Surgery, University of Wales College of Medicine, Cardiff, UK*

Background Matrix metalloproteinases (MMPs) are crucial for the invasion and metastasis of breast tumour cell lines. The initial steps of angiogenesis also require basement membrane degradation and matrix protein remodelling. Production of these MMPs by fibroblasts is induced by breast carcinoma cell lines. Pollette *et al.* found that the invasive breast cell line MDA231 induced breast fibroblasts to produce MMP-1 and activate pro-MMP-2, but the less invasive cell line MCF-7 did not. Assessment of the angiogenic activity of these two cell lines in co-culture with fibroblasts, using the chick chorioallantoic membrane (CAM) model system, is presented.
Methods Using stereoscopic microscopy blood vessels invading a 20-μl collagen gel on the CAM were counted through a 2 × 2 mm nylon mesh over 5 days. MDA231 and MCF-7 cells were co-cultured on these gels with the slow-growing fibroblast cell line KB16F. Results are expressed as a percentage of mesh squares containing blood vessels.
Results MDA231 cells were more angiogenic when co-cultured with a fibroblast cell line that was not significantly angiogenic by itself. MCF-7 cells showed no such angiogenic advantage with fibroblasts.

Assay	*n*	Angiogenesis (%)	*P**
KB16F *versus* negative control	72	20 *versus* 18	0·135
MDA co-culture *versus* MDA alone	33	100 *versus*85	0·028
MCF-7 co-culture *versus* MCF-7 alone	54	85 *versus* 75	0·676

Values are median. *Mann–Whitney *U* test

Conclusion This breast fibroblast cell line is slow growing and displays contact inhibition *in vitro*. When incubated in isolation on the chick CAM it does not demonstrate significant angiogenic properties against negative controls. The co-culture of MDA231 cells and breast fibroblasts attracts a significantly better blood supply than MDA231 cells alone, unlike the MCF-7 cells. The precise role of MMPs in this tumour stroma interaction needs further investigation and raises the possibility that inhibition of MMP function could have a dual role in delaying tumour progression *in vivo*.

Analysis of the survival advantage to specialist treatment of breast cancer

D. B. Kingsmore, D. Hole*, C. R. Gillis* and W. D. George, *Department of Surgery, Western Infirmary and *West of Scotland Cancer Surveillance Unit, Glasgow, UK*

Background Before screening, treatment by a specialist was reported to confer a survival advantage. The aim of this study was to investigate whether the survival advantage persisted with longer follow-up and to determine if it could be explained by adjuvant therapy.

Methods All 5625 cases of invasive breast cancer in a defined geographical area from 1980 to 1994 were identified and the original pathology reports obtained. Cause of death was obtained from the Registrar General. The survival of women treated by a specialist was compared with that of women treated by non-specialists using Cox's proportional hazards model.

Results Survival in all groups treated by the specialist unit was significantly better, except in those with tumours greater than 40 mm (*Table*). In node-positive women, the survival advantage seen was greater in women aged 50–74 years than in those aged less than 50 years.

	Specialist		Non-specialist			
	5 years*	10 years*	5 years*	10 years*	Relative hazard ratio	*P*
Tumour size (mm)						
0–19	90	81	81	70	0·57 (0·41–0·80)	< 0·001
20–39	75	59	68	52	0·78 (0·63–0·96)	0·02
40 +	52	37	50	36	0·93 (0·71–1·20)	n.s.
Nodal status						
Negative	88	79	84	72	0·76 (0·58–0·99)	0·047
Positive	66	50	54	37	0·68 (0·56–0·81)	< 0·001
Age of node-positive women (years)						
< 50	65	47	54	41	0·72 (0·51–1·00)	n.s.
50–74	67	51	54	35	0·66 (0·53–0·82)	< 0·001

*Values are survival rates (%). Values in parentheses are 95 per cent confidence intervals. n.s., Not significant

Conclusion The survival advantage associated with specialist treatment persists and indicates a higher cure rate. This advantage exceeds any benefit from adjuvant therapy and is seen in women who would not be eligible for chemotherapy.

Expression of thrombospondin 1 in invasive breast cancer: its association with p53 status, angiogenesis and clinical outcome

M. A. Steward, A. J. Rice, C. Quinn, E. A. Benson and K. Horgan, *Departments of Surgery and Histopathology, The General Infirmary at Leeds, Leeds, UK*

Background Angiogenesis is an important process in tumour progression. Thrombospondin 1 (TSP-1), an extracellular matrix glycoprotein, has been shown to have antiangiogenic properties. However, some studies have demonstrated an inhibitory role. Recent studies have shown an inverse relationship between TSP-1 expression and p53 status in cultured fibroblasts. The significance of this and its relevance to clinical outcome in invasive breast cancer is poorly understood. The role of TSP-1 expression, p53 status and microvessel density as a measure of angiogenesis has been examined in invasive breast cancer.

Methods Formalin-fixed paraffin-embedded tissue sections from 48 consecutive invasive breast cancers were examined immunohistochemically for TSP-1 and p53 expression. Microvessel density was estimated using CD31 endothelial cell antibody. The findings were correlated with recurrence-free and overall survival.

Results There was a significant correlation between TSP-1 expression and microvessel density ($P < 0\cdot03$) with high levels of TSP-1 expression found in conjunction with low microvessel density counts. High microvessel density was correlated with p53 positivity ($P < 0\cdot01$) and both microvessel density and p53 positivity were significantly correlated with recurrence-free survival and overall survival ($P < 0\cdot03$). However, TSP-1 expression was not significantly associated with recurrence-free or overall survival and there was only a loose non-significant inverse relationship between TSP-1 expression and p53 status.

Conclusion These results support the concept that TSP-1 expression has an antiangiogenic role in invasive breast cancer. These data also confirm that tumour microvessel density and p53-positive status are markers of poor clinical outcome. However, TSP-1 expression does not afford a survival advantage in invasive breast cancer nor does it exhibit an inverse relationship with p53 status.

Surgical introduction of endotoxin increases metastatic growth and circulating levels of vascular endothelial growth factor

G. Pidgeon, J. Harmey, E. Kay*, H. P. Redmond and D. J. Bouchier-Hayes, *The Royal College of Surgeons in Ireland, Departments of Surgery and *Pathology, Beaumont Hospital, Dublin, Ireland*

Background Surgical resection of primary tumours may paradoxically induce rapid growth of distant metastases through an angiogenic mechanism. Wound factors are usually regarded as the stimulus for vessel growth; however, these appear late in the circulation. It was hypothesized that endotoxin lipopolysaccharide (LPS) introduced at the time of surgery stimulates immune and tumour cell production of vascular endothelial growth factor (VEGF), a potent angiogenic factor, contributing to increased growth of metastases.

Methods Fifty Balb/c mice were injected with 1×10^5 4T1 mammary adenocarcinoma cells by tail-vein injection. On day 14 the animals received either anaesthesia alone, laparoscopy with carbon dioxide, laparoscopy with air, laparotomy, saline injection or LPS injection ($10\,\mu\text{m ml}^{-1}$). On day 5 following surgery or injection, lungs were excised and weighed as an indication of metastatic burden. Serum VEGF was assayed by enzyme-linked immunosorbent assay.

Results There was a significant increase in metastatic burden between the air laparoscopy and laparotomy groups compared with either controls or the carbon dioxide laparoscopy group. Similarly, metastatic burden was increased in the endotoxin group compared with saline controls. Mitotic index within the metastases and serum VEGF levels were significantly higher following endotoxin injection and either laparotomy or air laparoscopy compared with the appropriate controls.

Group ($n = 8$)	Metastatic burden	Mitotic index	Serum VEGF (pg ml^{-1})
Control (anaesthesia)	1·32(0·12)	4·39(0·63)	14·28(5·44)
Carbon dioxide laparoscopy	1·94(0·42)	4·71(0·15)	28·41(13·70)
Air laparoscopy	2·73(0·12)*	7·99(0·09)*	61·97(7·14)*
Laparotomy	3·37(0·14)*	8·33(0·21)*	77·92(5·00)*
Saline	1·99(0·10)	4·74(1·71)	33·88(7·34)
Endotoxin (10 μg ml^{-1})	2·84(0·20)†	7·68(0·42)†	207·85(42·74)†

Values are mean(s.d.). *$P < 0\cdot0001$ *versus* anaesthesia control; †$P < 0\cdot0003$, ‡$P < 0\cdot05$ *versus* saline.

Conclusion Open surgery induced higher rates of metastatic growth and raised levels of circulating VEGF compared with controls. Air laparoscopy and endotoxin injection led to a similar effect, with no significant effect observed when the peritoneum was sufflated with sterile carbon dioxide. This indicates that endotoxin introduced during open surgery may increase both tumour growth and angiogenesis. Therefore by reducing surgical exposure to LPS it may be possible to attenuate postoperative metastatic tumour growth.

Human tumour-derived endothelial cells exhibit decreased expression of Bcl-2 and Bag-1 and are more susceptible to interferon γ-induced apoptosis and antiangiogenesis

J. H. Wang, Q. D. Wu, H. P. Redmond, C. Condron and D. Bouchier-Hayes, *The Royal College of Surgeons in Ireland, Department of Surgery, Beaumont Hospital, Dublin, Ireland*

Background Solid tumour growth and metastasis are dependent on the formation of new blood vessels (angiogenesis). Studies based on intact vessels or established cell lines have shown that tumour and normal blood vessels differ in their permeability and composition of the basement membrane. However, further investigation of these differences with potential significance for innovative therapeutics of tumour vascular targeting have been hindered because of the lack of readily available and purified human tumour-derived endothelial cells (HTDECs) for analysis. This study was carried out to establish the technique for isolation and identification of HTDECs and normal human vascular endothelial cells (HVECs).

Methods HTDECs were freshly isolated from human colorectal tumours ($n=5$) using collagenase and DNAase digestion, and Percoll gradient sedimentation. HTDECs were identified and confirmed by their angiotensin-converting enzyme activity, positivity for von Willebrand factor-related antigen staining, and typical capillary-like formation on Matrigel. HVECs were isolated from human umbilical veins ($n=6$). The expression of adhesion molecules on HTDECs and HVECs was assessed by flow cytometry. Expression of antiapoptotic gene proteins, Bcl-2 and Bag-1, was detected by Western immunoblotting. HTDEC and HVEC proliferation, capillary tube formation and apoptosis were also evaluated.

Results Both HTDECs and HVECs had similar expression of PECAM-1. However, HTDECs expressed high levels of intercellular adhesion molecule 1 (ICAM-1) and E-selectin compared with HVECs ($P<0{\cdot}05$). P-selectin was absent in normal HVECs, but was detected in HTDECs. As a result, the spontaneous adhesion of human lymphocytes to HTDECs was higher than to HVECs (27 *versus* 16 per cent, $P<0{\cdot}05$). Treatment of HTDECs with interferon (IFN) γ 250 units ml^{-1} for 24 h resulted in significant increases in inhibition of cell proliferation (72 per cent inhibition of control) and in cell apoptosis (31 per cent) compared with IFN-γ-treated HVECs (proliferation 38 per cent inhibition of control; apoptosis 15 per cent). IFN-γ markedly inhibited HTDEC capillary tube formation on Matrigel. Western blotting revealed that HTDECs expressed lower levels of Bcl-2 and Bag-1 gene proteins than normal HVECs.

Conclusion These studies confirm firstly the upregulation of ICAM-1 on HTDECs and the consequent increased lymphocyte adherence. The observations of decreased antiapoptotic gene protein, bcl-2 and bag-1 expression, and the associated increase in IFN-γ-induced apoptosis and antiangiogenesis in HTDECs may have implications for the design of new anticancer therapies.

Lipopolysaccharide-mediated upregulation of vascular endothelial growth factor in macrophages and tumour cells

D. A. McNamara, G. Pidgeon, J. Harmey, T. N. Walsh, H. P. Redmond* and D. J. Bouchier-Hayes, *The Royal College of Surgeons in Ireland, Department of Surgery, Beaumont Hospital, Dublin and *Department of Surgery, University College Hospital, Cork, Ireland*

Background Angiogenesis is an important determinant of tumour proliferation and vascular endothelial growth factor (VEGF) is the most potent angiogenic factor known. The authors have shown that exposure to airborne endotoxin (lipopolysaccharide (LPS)) during surgery results in increased serum VEGF levels in a tumour-bearing murine model. The aim of this study was to determine the source of VEGF following macrophage and tumour cell exposure to LPS.

Methods Peritoneal macrophages isolated from LPS-sensitive (HEN) and LPS-resistant (HEJ) mice were adhered and stimulated *in vitro* with LPS (1–100 ng) for 24 h. Murine 4T1 mammary adenocarcinoma cells were cultured similarly. Human monocytes were isolated, matured to macrophages *in vitro* and activated with interferon γ before incubation with LPS 1–100 ng for 24 h. VEGF messenger RNA (mRNA) expression was determined semiquantitatively by reverse transcriptase–polymerase chain reaction and VEGF protein levels were determined by enzyme-linked immunosorbent assay.

Results VEGF mRNA and protein expression were not significantly altered in LPS-stimulated peritoneal macrophages isolated from LPS-sensitive or LPS-resistant mice. Human macrophage VEGF mRNA expression was increased in response to LPS in a dose-dependent manner. Mammary carcinoma cell production of VEGF following LPS stimulation was upregulated.

Conclusion In the murine model, LPS upregulates VEGF production by tumour cells but not by macrophages. In contrast, human macrophages increase VEGF production following LPS exposure. This may reflect the differential expression of CD14 LPS receptor between human (positive) and murine (negative) macrophages. Perioperative exposure to LPS may stimulate angiogenesis following surgery generating a permissive environment for tumour growth.

Omeprazole-induced hypergastrinaemia promotes the progression of adenomas and decreases survival in the *Min* mouse model of familial adenomatous polyposis

A. M. Smith, J. D. Hardcastle and S. A. Watson, *The Academic Unit of Cancer Studies, Department of Surgery, Nottingham University, Nottingham, UK*

Background Gastrin is a potent mitogen for colorectal epithelium and tumours. Overexpression of the gastrin receptor has been shown in hyperproliferative colonic epithelium and all grades of adenomas. Thus a state of hypergastrinaemia may promote progression through the adenoma–carcinoma sequence. The effect of omeprazole-induced hypergastrinaemia on the progression of intestinal neoplasia was determined in the *Min* (multiple intestinal neoplasia) mouse model of polyposis coli.

Methods Mice were entered into the study when polymerase chain reaction analysis confirmed the Min^{+} genotype. *Min* mice were randomized into four groups to receive: omeprazole (75 mg kg^{-1} daily oral treatment); omeprazole + Gastrimmune (a gastrin immunogen inducing the *in situ* formation of antigastrin antibodies, 100 μg per mouse on day 0 and every 3 weeks); control mice received oral vehicle control with or without a control immunogen. Serum gastrin levels were measured by radioimmunoassay. Before termination, 5-bromo-2′-deoxyuridine was administered to generate a proliferative index.

Results Treatment with omeprazole produced serum gastrin levels of 236 pg ml^{-1} compared with 67 pg ml^{-1} in the untreated group. Hypergastrinaemia significantly decreased survival compared with the appropriate control ($P=0{\cdot}0001$, log rank test), with mice in the control group having a 50 per cent survival of 9·5 weeks compared with 6 weeks in the omeprazole group. Gastrimmune induced the formation of serum antibodies with an antigen binding capacity of more than 20 ng ml^{-1} resulting in effective neutralization of the hypergastrinaemic state. Gastrin neutralization resulted in a reversal of the survival disadvantage induced by omeprazole ($P=0{\cdot}0017$). The hypergastrinaemic mice had enhanced proliferation of normal colonic mucosa (9·5 per cent proliferating cells increased to 20·1 per cent; $P<0{\cdot}05$, Mann–Whitney U test) and colonic neoplasia (22·3 per cent increased to 35·0 per cent, $P<0{\cdot}01$).

Conclusion The level of hypergastrinaemia was in the range attained in humans on a maintenance dose of omeprazole and resulted in enhanced progression through the adenoma–carcinoma sequence. Gastrin was confirmed as the mediator inducing a state of hyperproliferation within both normal and neoplastic colonic epithelium. This study highlights the need to reassess the safety of hypergastrinaemia.

Thermal preconditioning attenuates no-reflow phenomenon: an intravital microscopy study

G. Chen, C. Kelly, H. Chen, A. Leahy and D. J. Bouchier-Hayes, *The Royal College of Surgeons in Ireland, Department of Surgery, Beaumont Hospital, Dublin, Ireland*

Background In previous studies, the authors have shown that induction of a 70-kDa heat-shock protein by thermal preconditioning (TP) attenuates microvascular injury caused by ischaemia–reperfusion (I–R). The most damaging consequence of prolonged I–R injury is the permanent occlusion of part or the whole of the microvasculature with resultant failure, the 'no reflow' phenomenon. The purpose of this study was to investigate the effect of TP on the postischaemic no-reflow phenomenon in postcapillary venules. No reflow is defined as the failure to observe forward flow in the mesenteric venule under intravital microscopic observation.

Methods Sprague–Dawley rats were randomized into an I–R group ($n = 15$) and TP + I–R group ($n = 14$). TP was induced by raising core body temperature to 41 ± 0·5°C for 15 min 18 h before I–R injury, which in turn was established by occlusion of the superior mesenteric and coeliac vascular pedicle for 30 min, followed by 60 min of reperfusion. Blood flow in a mesenteric postcapillary venule (22–35 μm) was measured by intravital microscopy. The mean systemic blood pressure (MSBP) was observed. Expression of the 70-kDa heat-shock protein was determined by Western immunoblotting.

Results Results are given for baseline (0 min), during ischaemia (I-30 min) and during reperfusion (R-10 and R-60 min).

	Blood flow (nl s^{-1})		MSBP (mmHg)	
	I–R	TP + I–R	I–R	TP + I–R
0 min	1·6(0·6)	2·0(0·5)	111·8(10·1)	109·7(8·7)
I-30 min	0·0(0·0)	0·0(0·0)	106·1(15·3)	103·7(15·5)
R-10 min	0·1(0·2)	0·6(0·4)*	74·7(16·6)	86·8(13·8)*
R-60 min	0·1(0·3)	0·7(0·7)*	71·4(15·9)	89·1(15·1)*

Values are mean(s.d.). *$P < 0·05$ (I–R *versus* TP + I–R, analysis of variance with Scheffe post hoc correction)

Occlusion of the vascular pedicle for 30 min resulted in the no-reflow phenomenon in 11 of 15 rats in the I–R group. This was associated with severe hypotension. Thermal preconditioning significantly reduced the incidence of no reflow (three of 14, $P < 0·05$). In addition, thermal preconditioning attenuated I–R-induced hypotension. This was associated with expression of the 70-kDa heat-shock protein.

Conclusion These data suggest that thermal preconditioning may be of value in treating the consequence of severe ischaemia.

Enteral nutrition is superior to parenteral nutrition in severe acute pancreatitis: results of a randomized prospective trial

Sir

Kalfarentzos *et al.* are to be congratulated for demonstrating that enteral nutrition may be administered with safety to patients with severe pancreatitis (*Br J Surg* 1997; **84**: 1665–9), but some of their conclusions should be discussed.

Targets for energy and nitrogen delivery, related to body mass, were determined but the mean daily intakes achieved were below this. Actual energy delivery was only three-quarters of that intended and no explanation was given. If feed reformulation would have allowed more complete nutrition by one route over another, the discrepancy might be of significance. Some patients developed diarrhoea, but it is unclear whether this was a consequence of the route of feeding and if the manner of feed delivery therefore was changed. Maintenance of nutritional status was the central aim of the study and was inferred from urinary nitrogen balance studies. In patients with severe pancreatitis substantial nitrogen loss occurs in the acute-phase response and as a consequence of pancreatic necrosis and its resection. Assessment of urinary nitrogen loss alone would seem insufficient to determine whole-body balance in this context. The authors stated that enteral and parenteral nutrition were equally effective to maintain lean body mass, but provided no evidence to support this. Body composition was not directly measured. It was implied that, because urinary nitrogen balance was similar in the two groups, lean body mass must have been similarly preserved; this is a bold assumption. Deduction of change in body composition from nitrogen balance is only possible when assessment of balance is complete and initial body composition is known[1]. No data regarding the nutritional status of the patients at inclusion in the study were provided. Accurate measurement of body composition in critically ill patients may be impossible because of practical limitations but muscle function is related to lean body mass and improved function may precede restoration of lean body mass when nutritional support is provided[2]. Non-dominant hand grip strength or FEV_1 (forced expiratory volume in 1 s) could perhaps have been assessed during the study.

2 Hill GL. Impact of nutritional support on the clinical outcome of the surgical patient. *Clin Nutr* 1994; **13**: 331–40.

Author's reply

Sir

We thank Mr Everitt for his comments on our study and will respond briefly to each point.

First, regarding target values for energy and nitrogen delivery *versus* actual values, we wish to point out that target values are expressed as total kcal per kg per day (Patients and methods: Randomization and nutrition methods) whereas actual energy delivery is expressed as non-protein kcal per kg per day (Results: Tolerance and nutrition data). The actual delivery, if expressed as total kcal per kg per day, is 29–30 and therefore not significantly different from target values. Protein delivery was also comparable to target value (1·43–1·45 g per kg per day *versus* minimum target value of 1·5 g per kg per day).

The incidence of diarrhoea was not significantly different between groups; we considered that this did not depend on the route of feeding, but rather on other factors. Neither the manner of feed delivery (continuous 24 h infusion in all patients) nor the rate of infusion were changed for this reason in any patient during the course of the study.

Finally, we agree that the use of nitrogen balance alone may not be the best way to determine lean body mass. However, this was the best method available to us at the time. We have no means of directly measuring body composition that would not only have been very expensive but, as Mr Everitt himself points out, extremely difficult if not impossible to perform accurately in these critically ill patients. Non-dominant hand grip strength and FEV_1 would have been equally difficult to assess.

Randomized controlled trial of open and closed haemorrhoidectomy

Sir

I read with interest the article by Ho *et al.* (*Br J Surg* 1997; **84**: 1729–30). We have been performing closed haemorrhoidectomy with local anaesthesia[1] for over 30 years and find the paper's conclusion unacceptable and the reported complication rate high.

The technique of closed haemorrhoidectomy described by the authors is not as performed by most surgeons in the USA and not as originally described by Ferguson and Heaton[2].

Diathermy deters from primary healing by first intention. Including small bites of internal sphincter during closure contributes to dehiscence by pulling away the approximated edges following inevitable sphincter contraction. A previous large series showed secondary haemorrhage in 14 of 2274 patients. Only five patients developed infection[3]. A postoperative bleeding rate of 6 per cent following open haemorrhoidectomy and 9 per cent following closed haemorrhoidectomy is unacceptably high. Faecal impaction following open haemorrhoidectomy can be avoided by administering an appropriate laxative.

The authors suggest that it is arguable whether the wound dehiscence rate of eight of 33 following closed haemorrhoidectomy would be less if fewer than three haemorrhoids were excised. It is our practice to remove three or more haemorrhoids and the haemorrhoidal tissue excised should allow for approximation of the cut edges without tension.

A comparison of the techniques is only valid if they are performed appropriately.

3 Khubchandani IT, Trimpi HD, Sheets JA. Closed hemorrhoidectomy with local anesthesia. *Surg Gynecol Obstet* 1972; **135**: 955–7.

Authors' reply

Sir
We are pleased that our paper stimulated the interest of Dr Khubchandani. We can understand his hesitancy over the use of diathermy, based on his retrospective experience. None the less, prospective controlled randomized data have shown that, with proper use, this technique was at least as safe as conventional scissors[1]. Furthermore, our wound dehiscence rate after closed haemorrhoidectomy (observed with strict prospective methodology) was not more than that previously reported in another controlled randomized study[2]. A comparison of results is only valid if the study methodologies and quality of data are equivalent.

Comparison of endoanal magnetic resonance imaging with surgical findings in perirectal sepsis

Sir
We enjoyed the article by Abar *et al.* relating to magnetic resonance imaging (MRI) of perirectal sepsis (*Br J Surg* 1998; **85**: 111–14), which again demonstrates the value of this technique for preoperative assessment. The authors chose to use an endoanal receiver coil, which increases spatial resolution in exchange for a limited field-of-view, and correctly state that disease lying beyond this will be undetectable. Indeed, failure to visualize a low fistula in one patient, and a supralevator collection with attendant extrasphincteric track in another, were blamed on this. This phenomenon is analogous to that encountered with anal endosonography, which may also miss disease beyond the focal range of the probe[1].

Initial reports of MRI in cryptoglandular fistula disease used a body coil[2], which does not suffer this disadvantage. Although spatial resolution is reduced and the separate components of the sphincter complex are not as well visualized, this does not seem to hinder fistula classification. Studies using body coils have achieved surgical concordance approaching 100 per cent[3,4]. We have recently completed a prospective comparison of a prototype endoanal coil (Philips Medical Systems, London, UK) and conventional body coil imaging in 30 subjects with complex cryptoglandular disease[5]. Surgical concordance for body coil imaging reached 96 per cent while endoanal imaging could only achieve 68 per cent due to field-of-view limitations similar to those cited by Zbar *et al.* Additionally, anal pain prevented coil insertion in five patients. Complex fistula disease is characterized by remote tracks and collections, intuitively suggesting that body coil examination may be preferable. To our knowledge, dedicated endoanal coils are not yet commercially available despite initial reports 3 years ago[6].

We do not want to devalue endoanal coils but fistula imaging is possible on the majority of commercially available MRI scanners without resorting to such equipment. Ultimately, examination employing both coils is likely to be the gold standard. We reserve endoanal imaging for 'troubleshooting' but radiological unfamiliarity with fistula classification far outweighs any difference between techniques.

Book reviews

Critical Care of the Surgical Patient. Companion Series to Bailey and Love's Short Practice of Surgery

G. C. Hanson (ed.). 282 × 223 mm. Pp. 454. Illustrated. 1997. New York: Chapman and Hall. Price not supplied.

Intensive care is an essential component of surgical practice. The advent of the intensivist has too often resulted in the surgical team being relegated to a back seat in the management of patients. It is, therefore, appropriate that a group of intensivists and enthusiasts from other disciplines, including surgery, have come together and written a very authoritative and readable text encouraging a team approach to the management of patients in the intensive therapy unit. At 450 pages in length with some heavy duty physics, this is not a book for light bedtime reading, but it is both informative and authoritative. I am sure that this volume will be useful for higher surgical trainees preparing for the intercollegiate examination as well as surgeons updating their knowledge or needing a reference book of intensive care practice. The text is comprehensive in its coverage, with sections on the management of intensive care equipment, and on the staffing and nursing of an intensive care unit. At the other end of the spectrum, the important ethical issues surrounding the management of critically ill patients are covered in some detail. The book is well illustrated and referenced. I would recommend this volume to all with an interest in the management of patients in intensive care. It should enable the surgeon to hold his own in discussion with the intensivist.

J. H. Scholefield

Queen's Medical Centre
Nottingham NG7 2UH
UK

Complications of Endoscopic and Laparoscopic Surgery: Prevention and Management

J. L. Ponsky (ed.). 285 × 220 mm. Pp. 292. Illustrated. 1997. Philadelphia, Pennsylvania: Lippincott-Raven. £95.50.

This book is a multiauthor text which states in its preface that its aim is to compile the complications of endoscopic and laparoscopic surgery, and to describe their prevention and management. It has 39 contributing authors and their styles are markedly different. Some of the chapters fulfil the overall aim of the book; other chapters are devoted almost entirely to descriptions of technique and some devote pages to the indications for procedures. Descriptions of procedures and their indications can be found in established texts on endoscopic and laparoscopic surgery. The subject of the book is of topical interest with the expansion of endoscopic and laparoscopic surgery, the increasing numbers of complications reported and their malpractice implications. The authors have covered the full spectrum of endoscopic and laparoscopic surgery. Many of the authors are well known in their field. I believe that postgraduate specialists would prefer a more detailed bibliography at the end of each chapter. The book would be improved if the authors itemized in the text specific references to support their quotation of various percentage complications. The text is written entirely from an American perspective and much of the terminology and abbreviations are USA orientated. Chapter 10 is out of style with the rest of the chapters in that it is almost a mini-paper. Chapter 11 is good, although incidences of abdominal wall hernia after surgery should be referenced. Chapter 26 is useful but the illustrations could be greatly improved. Overall, there is a place for this text. However, it is unlikely to be purchased by individual postgraduate trainees or by many general surgeons, although it will appeal to specialized endoscopic surgeons. It would be a useful text for libraries.

Hamilton Bailey's Physical Signs. Demonstrations of Physical Signs in Clinical Surgery. 18th ed.

J. S. P. Lumley (ed.). 245 × 188 mm. Pp. 518. Illustrated. 1997. Oxford: Butterworth-Heinemann. £39.50.

Since its first edition in 1927 this book has been a standard text for both undergraduates and postgraduates. This latest edition is the most radical revision that has been undertaken during those 70 years, containing 40 chapters written by 14 authors. It has a comprehensive index and has been redesigned with more than 1000 new full-colour photographs. There are new chapters on multiple injury, tropical disease and AIDS. Inevitably, this has meant change that not all will appreciate. Although old and black and white, some previous illustrations were classics of their time and I do mourn the passing of the foonotes which I consider imparted useful information.

The content of the chapters varies. The one on breast disease itemizes staging by the International and tumour node metastasis classifications, but such classification is lacking for other tumours. Some authors have gone beyond the demonstration of physical signs, discussing presentation, pathology, prognosis and even giving brief outlines of treatment. When this has occurred, to remain compact, the account has been dogmatic with little discussion of alternative views. In an era of increasing specialization, this can be disadvantageous and it would be safer to adhere strictly to the original concept of the demonstration of physical signs. I received this volume 2 weeks before examining for the AFRCS (Ed) and, during the clinical examinations, it crossed my mind several times that a number of candidates would have done well to have read this book beforehand. Professor Lumley and his coauthors are to be congratulated on ensuring that this tried and tested work will have a secure future in the next millennium.

Instructions to authors

The British Journal of Surgery publishes original articles, reviews and leading articles. All manuscripts are submitted to editorial review.

An article is reviewed for publication on the understanding that the work it reports has not been submitted simultaneously to another journal, has not been accepted for publication elsewhere and has not already been published. **Any detected attempt at dual publication will lead to automatic rejection and may prejudice acceptance of future submissions.** To avoid subsequent embarrassment, please submit with your manuscript copies of any other papers, either published, in press, or submitted for consideration elsewhere, which relate to the same subject. It is essential that you submit any other publications or submissions using the same data set to the Editors to allow assessment of any potential overlap with the submission to the Journal. Indicate on the title page whether the paper is based on a previous communication to a society or other meeting. Articles and their illustrations become the property of the Journal unless rights are reserved before publication.

Send four copies of original articles and other editorial matter to: The Editor, *The British Journal of Surgery*, Blackwell Science Ltd, 25 John Street, London WC1N 2BL, UK. Telephone: 0171 404 1831. Facsimile: 0171 404 1927. Books for review should be sent to the same address.

A covering letter must accompany all submissions and must be signed by all authors. State in the covering letter whether an abstract of the work has been published and give an appropriate reference on the title page. Disclose in the covering letter any potential or actual personal, political or financial interest you may have in the material, information or techniques described in the paper. The decision to publish or withhold such information will be made by the Editors. Acknowledge all sources of financial support for the work. The first named author is responsible for ensuring that all authors have seen and approved the manuscript and are fully conversant with its contents. The Journal accepts the criteria for authorship proposed in the *British Medical Journal* (*BMJ* 1994; **308**: 39–42). When a paper has many authors (i.e. more than six), you may be asked to justify the inclusion of all names listed. Results of multicentre studies should be reported under the name of the organizing study group. Methods of recognizing contributors have been proposed (*Lancet* 1995; **345**: 668).

Disks

Following final approval of articles, you will be asked to submit the accepted version on disk. These should be IBM-compatible. An accurate hard copy must accompany each disk, together with details of the type of computer used, software, and disk system if known. **Do not justify.** Please send us digital versions of your figures. Ideally, these should be sent in native format or WMF if created in Windows. Files saved as PS, EPS, GIF and TIF may also be used, but please note that it may not be possible to modify them. Avoid using tints if possible; if they are essential, try to make them coarse. Further details can be obtained from the publisher. Disks will not be returned to authors.

Rejected manuscripts and illustrations will not normally be returned.

Ethics

The Journal publishes all material relating to human investigation and animal experiments on the understanding that the design of the work has been approved by local ethics committees or that it conforms to standards currently applied in the country of origin. The Journal further reserves the right not to publish an article on the grounds that appropriate ethical or experimental standards have not been reached. Written consent must be obtained from the patient, legal guardian or executor for publication in *The British Journal of Surgery* of any details or photographs that might identify an individual. Submit evidence of such consent with the manuscript.

Preparation of manuscripts

The British Journal of Surgery subscribes to the policy of uniform requirements for manuscripts, which is designed to permit authors to resubmit papers to journals without extensive recasting. Authors are advised to consult the *New England Journal of Medicine* 1997; **336**: 309–15, or to obtain the leaflet 'Uniform Requirements for Manuscripts Submitted to Biomedical Journals' from The Editor, *British Medical Journal*, BMA House, Tavistock Square, London WC1H 9JR, UK (cost £1.00 per copy).

Authors are responsible for the accuracy of their report including all statistical calculations and drug doses. **When quoting specific materials, equipment and proprietary drugs, state in parentheses the brief name and address of the manufacturer.** Failure to do so will result in delay in publication as the Journal believes that this information is essential for any reader who wishes to obtain similar material. Generic names should normally be used.

Original articles

Original articles should normally be in the format of introduction, methods, results, discussion. Each manuscript must have a 200-word structured abstract. Lengthy manuscripts are likely to be returned for shortening. The discussion in particular should be clear and concise and should be limited to matters arising directly from the results. Avoid discursive speculation. **Randomized clinical trials** should be clearly identified as such in the title and abstract.

Reviews

The Editorial Board of *The British Journal of Surgery* encourages submission of review articles on topics of interest to its readers. Any topic will be considered, but priority will be given to those addressing a major current problem. The author of each accepted review will receive an honorarium. Potential authors are advised to contact: Mr J. A. Murie, University Department of Surgery, The Royal Infirmary, Edinburgh EH3 9YW, UK.

Leading articles

The Editors commission signed leading articles which are 600–900 words in length and address controversial topics of current interest. They should be supported by no more than ten key references. Submissions may be subjected to external review and assessment by the Editorial Board before acceptance. The Editors retain the right to alter style and shorten material for publication. An honorarium is payable on publication.

Correspondence

The Editors welcome topical correspondence relating to articles published in the Journal. Letters should not exceed 250 words and should be typed double-spaced.

Typescripts

Manuscripts must be clearly reproduced with adequate space for editorial notes. **Type or print the text on one side of sheets of A4 paper (210 × 297 mm) with double spacing and 4-cm margins. Manuscripts that do not conform to these requirements will be returned to you for recasting.** Begin each section (abstract, introduction, patients and methods, results, and discussion) on a new page.

Title page

On the title page give: (1) the title of the article; (2) the name and initials of each author; (3) the department and institution to which the work should be attributed; (4) the name, address, and telephone, facsimile and e-mail numbers of the author responsible for correspondence and to whom requests for reprints should be addressed; (5) sources of financial support; and (6) the category in which the manuscript is being submitted (original article, review etc.).

Abstract

This should be not more than 200 words on the second page of the manuscript and be presented in a structured format. **Background:** state why the study was done, and its main aim; **Method:** describe patients, laboratory material and other methods used. Clearly identify the nature of the study: randomized controlled trial, retrospective review, experimental study, etc. **Results:** state the main findings of the study; include important numerical values. **Conclusion:** state the main conclusion drawn from the results. Controversial or unexpected observations may be highlighted, but keep this section brief. Write the abstract in clear prose.

Tables and illustrations

Submit three copies of all illustrations and tables. Type each table on a separate page with an appropriate brief title. Line drawings are acceptable as clear black on white graphics, computer printout or photocopies. Submit radiographs, photomicrographs, etc unmounted in the form of glossy prints, original transparencies or negatives. If you include photocopies, they should be of sufficient quality to enable the Journal's referees to judge their content and value. Label each illustration on the reverse side giving its number (to correspond with its reference in the text) and the name(s) of the author(s); indicate the top of the illustration. Include a measure of magnification of photomicrographs. Illustrations should be drawn and labelled appropriately for reduction to one or two column widths of the Journal. Include explanations of symbols and shading in the legend. Survival curves should be accompanied by a table giving the actual numbers of patients involved. Include in the legends to illustrations and the footnotes to tables brief but comprehensive explanations of all the information presented. Look at recent issues of the Journal for examples of accepted layout. If a table or an illustration has been reproduced from a published work give the original source in full. Obtain permission to use published work from the original author and the publisher before submission.

Abbreviations

Use abbreviations sparingly. Terms that are mentioned frequently may be abbreviated but only if this does not impair comprehension by the reader. Use abbreviations consistently throughout the text and clearly define each one on first use.

Numbers and units

Use the decimal point, not a comma, e.g. 5·7. Use a space and not a comma after thousands and multiples thereof, e.g. 10 000. Use SI units (International System of Units) except for the measurement of blood pressure (mmHg). Where measurements were made in non-SI units, give the actual values and units, with SI equivalents inserted in parentheses at appropriate points.

Statistics

For detailed guidance on the handling of statistical material, consult *Br J Surg* 1991; **78**: 782–4. In evaluating a manuscript the Editors and statistical referees will consider the design of the study, the presentation and analysis of data and the interpretation of results.

Design

Set out clearly the objectives of the study, identify the primary and secondary hypotheses, and the chosen end-points, and explain the rationale for the choice of sample size. Investigators embarking on randomized controlled studies may wish to consider the CONSORT statement (*JAMA* 1996; **276**: 637–9).

Presentation

Whenever possible use graphical presentation to illustrate the main findings of a study. The use of standard deviation and standard error should be clearly distinguished. Do not use the '±' symbol; these statistics should be presented in parentheses after the mean value.

Analysis

Clearly describe which methods were used for which analyses; any methods not in common usage should be supported by references. Report results of statistical tests by stating the value of the test statistic, the number of degrees of freedom and the *P* value, e.g. '$t = 1{\cdot}34$, 16 d.f., $P = 0{\cdot}20$'.

Actual *P* values should be reported to two decimal places, especially when the result is not significant, rather than stating 'not significant'. Whenever possible, the results of the primary analyses should be reported using confidence intervals instead of, or in addition to, *P* values.

Interpretation

Do not confuse statistical significance with clinical significance. In particular, 'negative' findings should be interpreted through the use of confidence intervals.

Beware of placing undue emphasis on secondary analyses, especially when they are suggested by an inspection of the data.

References

Type the references with double spacing in the Vancouver style (see above: Uniform Requirements for Manuscripts Submitted to Biomedical Journals). Reference to abstracts from meetings is discouraged. Reference to unpublished communications will not be accepted. Cite personal communications in the text, in parentheses. The first author is responsible for confirming the acceptability of the material quoted with the originator.

In the text, number the references consecutively by superscript: ^{1} or $^{1-3}$. References cited only in tables or figures should be numbered in sequence according to the first mention of the table or figure in the text. The sequence for a standard journal article should be: author(s); title of paper; journal name abbreviated as in Index Medicus (written in full if no abbreviation is quoted); year of publication; volume number; page numbers. For example: De Bolla AR, Obeid ML. Mortality in acute pancreatitis. *Ann R Coll Surg Engl* 1984; **66**: 184–6. The sequence for the chapters of a book should be: author(s); chapter title; editors; book title; place of publication; publisher; year of publication; page numbers. For example: Calenoff L, Rogers L. Esophageal complications of surgery and lifesaving procedures. In: Meyers M, Ghahremani G, eds. *Iatrogenic Gastrointestinal Complications*. New York: Springer, 1981: 123–63.

Association of Surgeons of Great Britain and Ireland

1998 MOYNIHAN TRAVELLING FELLOWSHIP

The Association of Surgeons of Great Britain and Ireland represents all general surgeons throughout the United Kingdom and the Republic of Ireland. An annual Travelling Fellowship up to the value of £4,000 is available by open competition to Specialist Registrars, or Consultants within 3 years of appointment, to enable them to broaden their education and to present and discuss their contribution to British and Irish surgery overseas.

Candidate must be residents of the United Kingdom or the Republic of Ireland but need not be either Fellows or Affiliate Fellows of the Association; however they should be engaged in general surgery or a sub-specialty thereof. A full Curriculum Vitae should be submitted giving details of past and present appointments and publications, together with a detailed account of the proposed programme of travel, costs involved and the objective to be achieved. Shortlisted candidates will be interviewed by the Scientific Committee of the Association who will pay particular attention to originality, scope and practicability of the proposed journey. The successful candidate will be expected to act as an ambassador for British and Irish Surgery and should be fully acquainted with the aims and objectives of the Association of Surgeons in its role in surgery. After the visit the successful candidate will be asked to address the Association at its Annual General Meeting.

Deadline for applications: **Friday 2 October 1998**

Applications (11 copies) and requests for information should be submitted to the Honorary Secretary, Association of Surgeons of Great Britain and Ireland, at the Royal College of Surgeons of England, 35/43 Lincoln's Inn Fields, London WC2A 3PN.

1998 OVERSEAS SURGICAL FELLOWSHIP

The Association of Surgeons of Great Britain and Ireland, jointly with the **British Journal of Surgery Society**, are offering £10,000 per annum to sponsor surgeons wishing to work on a short term basis, primarily in the Third World. The purpose of this Scheme is to provide training and support for overseas medical schools in the development of their undergraduate and postgraduate training programmes and also for research, thereby, establishing links with these centres.

Only Fellows including Full, Senior, Associate and Affiliates of the Association of Surgeons may apply and if successful, a maximum of £2,000 will be made available to individual applicants.

Deadline for applications: **Friday 2 October 1998**

Further details are available from
Mrs N Lewis, The Association of Surgeons of Great Britain & Ireland, at the Royal College of Surgeons, 35/43 Lincoln's Inn Fields, London WC2A 3PN. Tel: 0171 973 0300; Fax 0717 430 9235.

Association of Surgeons of Great Britain and Ireland

The British Journal of Surgery is pleased again to have the opportunity of publishing the abstracts of the work presented at the Annual Scientific Meeting of the Association of Surgeons of Great Britain and Ireland. The pages which follow contain 317 abstracts, selected from a bumper total of 577 submitted, a fine testament to the health and vigour of scientific surgery within these islands.

The whole of general surgery is represented, with oral presentations on the following topics: vascular 55, coloproctology 33, general 31, upper gastrointestinal 24, breast 24, hepatobiliary & pancreatic 18, transplant/endocrine 9, and 7 abstracts for the Moynihan Prize session. In addition, there are 116 abstracts of poster presentations.

The October 1998 issue of the *British Journal of Surgery* will contain full papers describing work first presented at the Annual Scientific Meeting of the Association in Edinburgh this year. These papers will be selected after peer review from manuscripts submitted from Fellows and their guests. The authors of the paper adjudged best will receive the Association's *BJS* Prize.

Both this supplement and the October issue of the Journal cement a long-term relationship between the *BJS* and the Association. Over the years this relationship has benefited both organizations and we believe that it will continue. In the meantime, the Editors hope you will find the present publication attractive and worthy of retention on your bookshelves. On behalf of my colleagues at the *BJS*, I wish all participants an enjoyable congress in Edinburgh.

John Murie
Joint Editor, BJS

Moynihan 001

The quantification of normal anal canal anatomy and sphincter defects using three-dimensional endoanal sonography

D.M. Gold, C.I. Bartram, S. Halligan, M.A. Kamm and W.A. Kmiot *Department of Surgery, Hammersmith Hospital, Du Cane Road, London, and Departments of Radiology and Physiology, St Mark's Hospital, Northwick Park, Harrow, Middlesex*

Background: Conventional anal ultrasound provides no information on sphincter anatomy in the longitudinal plane. Using three-dimensional endoanal ultrasound we have studied whether longitudinal differences exist between normal male and female anal sphincters and explored the potential relationship between radial degree of a sphincter defect and its length.
Method: Twenty normal subjects and 24 faecally incontinent patients (25 external and five internal sphincter defects) underwent scanning and reconstruction to produce sagittal and coronal images of the anal sphincters to facilitate measurement. The radial degree of each sphincter defect was related to its longitudinal extent.
Results: The male anal canal was longer than in the female: $32{\cdot}6\pm5{\cdot}3$* mm compared with $25{\cdot}1\pm3{\cdot}4$* mm, $P<0{\cdot}001$**. The male internal anal sphincter (IAS) was longer than the female: $25{\cdot}6\pm6{\cdot}3$* mm and $19{\cdot}8\pm4{\cdot}0$* mm, respectively, $P<0{\cdot}02$**. However, mean IAS length as a percentage of total anal canal length was not different; 78·3 per cent ± 8·2 per cent* and 78·7 per cent ± 9·0 per cent*, respectively, $P<0{\cdot}91$**. The male anterior external anal sphincter (EAS) was longer than the female; $32{\cdot}6\pm5{\cdot}3$* mm and $15{\cdot}3\pm2{\cdot}8$* mm, respectively, $P<0{\cdot}0001$**; as was the anterior EAS as a percentage ratio of total anal canal length 100 per cent (100 per cent–100 per cent)§ and 62·9 per cent (53·8–70·7 per cent)§, respectively, $P<0{\cdot}0001$§§. The radial angle of sphincter defect related to length for the 25 EAS and the five IAS defects gave R^2 values of >80·0 per cent. $P<0{\cdot}0001$ for both.†
Conclusion: These data explain why certain women are predisposed to faecal incontinence after seemingly trivial obstetric or surgical trauma.
* = standard deviation; ** = unpaired *t* test; § = median and interquartile range; §§ = Mann–Whitney U-test; † = analysis of variances.

Moynihan 002

Metabolic consequences of radical curative resection for gastric cancer: total vs subtotal gastrectomy

G.V. Miller, J.B. Davies, S.M. Young, G. Young, D. Johnston and H.M. Sue Ling *Department of Surgery and Centre for Digestive Diseases, Leeds General Infirmary, Leeds*

Background: Subtotal gastrectomy for gastric cancer is reputed to be a safer alternative to total gastrectomy 'en principe' and is suggested to afford a better long-term nutritional outcome because of the presence of the small gastric remnant. We assessed the long-term nutritional outcome of patients after subtotal or total gastrectomy for gastric cancer to test this hypothesis.
Method: Fifty patients with no evidence of recurrent disease were recalled for assessment 5–15 years after curative resection for gastric cancer. Biochemical and anthropometric variables were measured in these patients and compared with data from 30 age- and sex-matched control subjects.
Results: The table below indicates median (interquartile range) values for each variable. Comparison between subgroups (control, total and subtotal gastrectomy) by sex was assessed using the Mann–Whitney U test.

	Control subjects		Total gastrectomy		Subtotal gastrectomy	
	M ($n=21$)	F ($n=9$)	M ($n=26$)	F ($n=7$)	M ($n=11$)	F ($n=7$)

Prealbumin (g/L)	22·9 (6·7)	23 (2·2)	20·1 (7·5)	17·4 (9·7)	19·1 (6·6)	19·8 (3·9)
CRP (mg/L)	0.64 (0·9)	0·55 (0·4)	0·56 (0·9)	0·61 (0·6)	1.1 (1.1)	0·76 (1·1)
Transferrin (mg/dL)	314 (59)	276 (98)	319 (87)	306 (184)	290 (139)	285 (112)

M = male; F = female; BMI = body mass index; CRP = C reactive protein.

Current weight and BMI were significantly lower than recall values for all patients after gastric resection, and significantly lower than controls. However, there was no significant difference in nutritional variables between patients undergoing total gastrectomy and subtotal gastrectomy or in control subjects.
Conclusion: The choice of surgical resection for gastric cancer should be dictated by tumour location, extent and oncological safety, and performed by suitably experienced surgeons, as long-term nutritional status is maintained at similar levels to control subjects, irrespective of type of resection.

Moynihan 003

A comparison of TGF β mRNA levels in renal transplant biopsies from patients immunosuppressed with cyclosporin or FK506

S.T. Williams, G.R. Bicknell*, P.N. Furness* and M.L. Nicholson *Departments of Surgery and *Pathology, Leicester General Hospital, Leicester*

Aims: TGF β, a fibrogenic cytokine thought to have an important role in the development of chronic allograft fibrosis following renal transplantation, may be upregulated by immunosuppression with cyclosporin. The aim of this study was to compare early TGF β gene expression in renal transplant recipients immunosuppressed with either cyclosporin or the new immunosuppressive agent tacrolimus (FK506).
Method: Renal transplant recipients received either Neoral cyclosporin 15 mg/kg/day ($n=19$) or tacrolimus 0·2 mg/kg/day ($n=19$). Tissue core transplant biopsies were performed 1 week, and 3, 6 and 12 months post-transplant. Single glomeruli were plucked from the surface of transplant biopsies and total mRNA was extracted using oligo DT dynabeads. Complementary DNA was synthesized by reverse transcription and the polymerase chain reaction (PCR) was used to amplify specific mRNA species. PCR products were quantified using an ELISA method and levels compared to the expression of a housekeeping gene. One hundred and eighty biopsies were analysed for the mRNA of TGF β, collagen type III, collagen IV (alpha 2 chain), tenascin, matrix metalloproteinase MMP2 and its inhibitors TIMP1 and TIMP2.
Results: TGF β expression correlated with collagen III ($r=0{\cdot}18$, $P=0{\cdot}015$), collagen IV alpha 2 ($r=0{\cdot}35$, $P<0{\cdot}1$), tenascin ($r=0{\cdot}73$, $P<0{\cdot}01$), TIMP1 ($r=0{\cdot}61$, $P<0{\cdot}01$) and TIMP2 ($r=0{\cdot}57$, $P<0{\cdot}01$), suggesting that TGF β is a fibrogenic influence in human renal transplants. However, there were no differences in the levels of mRNA for TGF β between recipients treated with cyclosporin (mean ± SEM = 0·09 u) and those treated with tacrolimus (mean ± SEM = 0·27 ± 0·06 u) ($P=0{\cdot}23$). In addition the whole blood levels of cyclosporin or tacrolimus did not correlate with mRNA levels of TGF β.

Conclusion: The technique described is a valuable tool in the investigation of early molecular events following renal transplantation. In this study there was no evidence for differences in the early expression of the gene for the profibrotic cytokine TGFβ between patients treated with cyclosporin or tacrolimus.

Moynihan 004

Marimastat inhibits neointimal thickening in a model of human vein graft stenosis

I.M. Loftus, K. Porter, M. Peterson, P.R.F. Bell, N.J.M. London and M.M. Thompson *Department of Surgery, University of Leicester, Leicester*

Background: Matrix metalloproteinases (MMPs) have been implicated in the development of vein graft stenosis, a process characterized by extensive remodelling and accumulation of the extracellular matrix. This study investigated whether marimastat (a non-specific MMP inhibitor) prevented myointimal hyperplasia in cultured human long saphenous vein.
Method: Eight segments of human vein were cultured in medium supplemented with therapeutic and supra-therapeutic doses of marimastat. Following 14 days of organ culture, one half of the tissue was homogenized and dialysed to extract MMPs, whilst the other half was prepared for histology. Neointimal thickness was measured by stereological analysis. Quantification of MMP2 and MMP9 was performed by gel enzymography.
Results: Neointimal thickness was significantly reduced in vein cultured with marimastat at 10^{-5} and 10^{-6}M concentrations when compared to control segments. Levels of MMP2 and MMP9 were significantly lower in vein cultured with marimastat at both concentrations. These results are summarized as follows (enzymography results shown as ratio to a control):

	Marimastat concentration			
	Control	10^{-5}M	10^{-6}M	*P* value
Neointimal thickness median (range) μm	22 (17–29)	4·5 (0–8)	7 (0–14)	$P<0·02$
MMP9	1·08 (0·57–1·57)	0·68 (0·37–0·91)	0·70 (0·47–0·96)	$P<0·05$
MMP2	1·18 (0·79–1·73)	0·67 (0·36–0·86)	0·81 (0·54–1·40)	$P<0·001$

Conclusion: Marimastat significantly reduced the level of MMF2 and MMP9 in this model of vein graft stenosis. This was accompanied by a significant reduction in neointimal thickening. Inhibition of MMPs therefore offers a pathway for pharmacotherapy to prevent vein graft stenosis *in vivo*.

Moynihan 005

Pathophysiology of postoperative lower limb compartment syndrome following prolonged pelvic surgery

A.F. Horgan, S.M. Geddes and I.G. Finlay *Department of Coloproctology, Glasgow Royal Infirmary University NHS Trust, Glasgow*

Background: Lower limb compartment syndrome (LLCS) is a rare, but devastating complication of prolonged pelvic surgery with little scientific information available regarding its pathophysiology.
Method: We studied 12 patients who underwent prolonged pelvic colorectal procedures in order to determine the intraoperative risk factors for developing LLCS. Blood flow to the lower limbs was monitored before, during and after surgery, by means of intra-arterial dorsalis pedis cannulation, laser Doppler flowmetry to skin and muscle, pulse oximetry and clinical observation. Recordings were taken every 15 minutes and on any alteration of the patient's position. Degree of elevation of the legs and head-down tilt was recorded, as was systemic blood pressure at all times.
Results: Mean operative time was 210 min (180 to 320 min). Good correlation was noted between laser Doppler index at skin level and arterial pressure in the dorsalis pedis. Oxygen saturation, on the other hand, did not correlate well with the other indices and gave consistently high readings (>96 per cent) until pulsatile flow to the foot ceased completely. Positioning the patient's leg in the lithotomy position did not lead to a significant decrease in foot perfusion. Addition of the head-down tilt, however, led to a rapid decrease in limb perfusion ($P<0·05$), with no pulsatile flow demonstrable on arterial line tracing and Doppler skin perfusion flux approaching zero, with clinically apparent ischaemia of the foot. These observations occurred despite a systemic arterial systolic blood pressure of >100 mmHg. Muscle blood flow in the anterior tibial compartment, as measured by laser Doppler flowmetry, revealed a ten-fold increase in perfusion index ($P<0·01$), which peaked in the second hour postoperatively, and occurred in the absence of any significant increase in skin perfusion or dorsalis pedis arterial blood pressure.
Conclusion: These data confirm the hypothesis that LLCS occurs as a result of a reperfusion injury confined to the muscle compartments. We suggest that hypotensive anaesthesia and Trendelenburg position are the major risk factors for LLCS and should be used for as short a period as possible during prolonged pelvic surgery.

Moynihan 006

Tracking of labelled monocytes during resolution of venous thrombi reveals their active recruitment from the vein wall

C.L. McGuinness, J. Humphries, A. Smith and K.G. Burnand
Department of Surgery, St Thomas' Hospital, London

Background: Monocytes are present in large numbers in mature human thrombi. The origin of these cells and the stimulus for their infiltration are unknown but it is unlikely that they are passively trapped as they only represent a small percentage of circulating white cells. The aim of this study was to track monocytic cells and discover the route by which they enter a thrombus.
Method: Home Office approval was obtained. A rat model of thrombosis was used. Rat mononuclear cell preparations were labelled with a red fluorescent phagocytic cell marker (PKH26-PCL). 10^7-labelled cells were injected intravenously immediately prior to thrombus induction. Whole blood, inferior cava containing thrombus and specimens from other organs were harvested at 1 h, 1, 2, 3 and 4 days, and 1, 2 and 6 weeks. Multiple contiguous frozen sections were processed for fluorescence microscopy and immunohistochemistry using the rat monocyte marker, ED-1.
Results: Fluorescent monocytes were found in the circulation for up to 1 week after infusion and their numbers in the thrombus increased from <5 per section, observed between 1 h and 3 days, to >100 per section at 1 week ($P<0·005$). At 3 days, fluorescent cells could be seen within the vasa vasorum and the surrounding tissue of the inferior vena cava. The proportion of monocytes seen in other tissues increased with time, but most fluorescent tissue monocytes were found in the lung and spleen.
Conclusion: Monocytes are actively recruited into thrombus between 3 and 7 days after thrombus formation, and they appear to enter from the vasa vasorum and surrounding tissues rather than the circulating blood adjacent to the thrombus. As monocytes produce plasminogen activators, their migration may be important in thrombus resolution.

Moynihan 007

Gut barrier failure in patients with acute pancreatitis

B.J. Ammori, P.C. Leeder, R.F.G.J. King, I.G. Martin, M. Larvin and M.J. McMahon *Leeds Institute for Minimally Invasive Therapy, The General Infirmary, Leeds*

Background: The aim of this study was to determine if gut permeability, measured within the first 48 h of admission, is increased in patients with acute pancreatitis and whether this correlates with disease severity.
Method: Intestinal absorption and renal excretion of polyethylene glycol

(PEG) 400 (micromolecule) and PEG 3350 (macromolecule) was measured to determine gut permeability changes. PEG 400 (5 g) and PEG 3350 (40 g) were administered enterally. Their detection in urine was achieved using high performance liquid chromatography. Patients were classified as having 'mild' or 'severe' disease according to the definitions of the Atlanta International Symposium of 1992. APACHE-II scores and C-reactive protein (CRP) were also determined on admission. Fifty-two patients (36 mild, 16 severe) and 12 healthy subjects were studied.

Results: Gut permeability to both molecules was significantly increased in patients with severe disease compared with mild disease and healthy controls. There was no significant difference in gut permeability to either molecule between patients with mild disease and controls.

	No. patients	Age (mean)	APACHE-II (median)	CRP (mean)	PEG 400 % retrieved (median)	PEG 3350 % retrieved (median)
Severe	16	57·5	10	250	60·7**	0·46**
Mild	36	54	7·5	95	11·1*	0·04*
Control	12	54	—	—	26·3	0·12

**Severe vs mild or control ($P<0{\cdot}001$, χ^2-test); *Mild vs control 'not significant'.

Conclusion: Gut permeability is significantly impaired in patients with severe acute pancreatitis and at an early stage of the disease. Breakdown in gut barrier function may play an important role in the development of complications of acute pancreatitis.

Endocrine/Transplantation 001

Adrenal cortical tumours in childhood

C.P. Driver, J. Birch, D.C.S. Gough and J. Bruce *Royal Manchester Children's Hospital, Pendlebury, Manchester*

Background: This study aimed to review the experience of adrenocortical tumours in the North West of England.
Method: A retrospective analysis of 18 children with a diagnosis of an adrenal cortical tumour in the 41-year period between 1954 and 1995, identified from the Manchester Children's Tumour Registry.
Results: Fourteen children had a carcinoma and four had an adenoma. The majority of patients had clinical signs of endocrine dysfunction at presentation, with virilization (11 patients) and a cushingoid appearance (eight patients) the commonest findings. Abnormal biochemical activity was identified in 16 tumours (94 per cent). The primary treatment in 17 patients was surgical. In addition, 12 children, all with carcinomas, had radiotherapy. Adjuvant chemotherapy was given to six patients, three of whom had mitotane (op-DDD). Of those children with a carcinoma 2 are dead, with a median survival of 52 months (range 1–317 months). The three second primary tumours all developed at sites within the field of previous radiotherapy, and proved fatal at 127, 176 and 317 months (median 207 months).
Conclusion: This series confirms the poor prognosis in adreno-cortical carcinoma in childhood, but a complete resection is compatible with cure from the primary disease. The frequency of second, fatal, primary tumours is of particular concern and long-term follow-up is mandatory in survivors, especially if radiotherapy was part of the treatment protocol.

Endocrine/Transplantation 002

Cathecolamine excretion from phaecromocytomas

R. Mihai, N. Wong*, M. Luckett*, E. Sheffield* and J.R.H. Farndon *University Department of Surgery and *Pathology, Bristol Royal Infirmary, Bristol*

Background: The aim of this study was to examine the pattern of cathecolamine secretion in patients with phaechromocytoma and correlate this with the ultrastructural morphology of the secretory granules in tumour cells.
Method: Fifteen patients with adrenal phaeochromocytomas ($n=\ 3$) or paragangliomas ($n=2$) (four men and 11 women, age 17–80 years were studied by measuring urinary-free noradrenaline (NA), adrenaline (Ad) and dopamine (DM). Histopathology examination and immunocytochemistry for specific markers chromogranin, S100, synaptophisin, neurofilament) confirmed the diagnosis. Electron micrographs (× 20000 were obtained from four random fields of each tumour (total surface ≈70 μm^2) and the number and type of secretory granules evaluated by two independent observers blind to the cathecolamine secretory pattern. Large round/elongated medium-density granules characterized adrenaline-type granules (Ad-G), while electron-dense granules lying in a vacuole were of the noradrenaline-type (NA-G).
Results: No correlation was found between NA output and the number/percentage of NA-G, although three tumours with normal NA output had only a minority of NA-G (22 ± 2 per cent). Ad-G were predominant (77 per cent of 173 granules/70 μm^2) in a tumour secreting only Ad but the percentage of Ad-G in six tumours with normal Ad output varied significantly (range 7–89 per cent). It was not possible to evaluate the granule type associated with DM secretion as a tumour secreting excessive amounts DM (14900 nmol/day) and Ad (1570 nmol/day) had a predominance of NA-G (63 per cent of 132 granules/70 μm^2) while in two other DM-secreting tumours (5500 and 4250 nmol/day, respectively) NA-G represented 93 per cent and 13 per cent, respectively. Two adrenal incidentalomas diagnosed as 'non-functional' phaechromocytomas expressed a high number of granules (99 and 172 granules/70 μm^2, respectively) predominantly of Ad type (>90 per cent). There was no significant difference between the number and type of granules evaluated by the two observers (χ^2 test).
Conclusion: Most phaechromocytomas contain a mixture of NA-G and Ad-G and the lack of correlation between cathecolamine secretion and the granularity suggest that other factors are involved in the control of secretion from these tumours.

Endocrine/Transplantation 003

Parathyroidectomy — experience with 170 consecutive cases

M. Menon, P.J. Drew, A. Macdonald, C.M.S. Royston and M.J. Kerin *Hull Royal Infirmary & Castle Hill Hospital, Kingston upon Hull*

Background: The aim of this study was to review the experience with parathyroidectomy performed in Hull over the last 10 years.
Method: A retrospective review of patients' case notes was performed utilizing histological data that had been collected centrally over this period. Presenting symptoms, preoperative investigations, operative findings, histology and biochemical and clinical outcome were reviewed.
Results: One hundred and seventy patients (median age 59 years, range 18–87, male:female, 54:116) underwent 176 parathyroidectomy operations during the study period. Hypercalcaemia was detected incidentally in 131 (77 per cent) asymptomatic patients, 25 (15 per cent) patients initially presented with renal colic, six (3·5 per cent) with psychiatric disturbance, five (3 per cent) with general malaise and three (1·5 per cent) with muscle weakness. Primary hyperparathyroidism was diagnosed in 136 (80 per cent) patients, secondary in 31 (18·5 per cent) and tertiary in three (1·5 per cent). Histology revealed: adenoma in 110, hyperplasia in 40 and carcinoma in one. Of the glands excised 27 were considered to be histologically normal. Six patients underwent re-exploration for persistent hypercalcaemia and five had further parathyroid tissue removed which was found to be normal in three patients, hyperplastic in two and an adenoma in one. One patient suffered a recurrent laryngeal nerve palsy following re-exploration. There were no other major complications in this series.
Conclusion: Primary hyperparathyroidism remains the commonest form of hyperparathyroidism. It is most commonly found incidentally and, in experienced hands, can be effectively and safely treated surgically.

Endocrine/Transplantation 004

Ultrasound-guided unilateral neck exploration compared with bilateral exploration in patients with sporadic primary hyperparathyroidism

B.J. Ammori, M. Madan, T.D. Gopichandran, J.J. Price, M. Whittaker, J.R. Ausobsky and R.M. Antrum *Bradford Royal Infirmary, Bradford*

Background: The aim of this study was to determine the accuracy of ultrasound (US) in preoperative localization of abnormal parathyroid gland(s) in patients with sporadic primary hyperparathyroidism undergoing initial neck exploration, and to compare results of US-guided unilateral neck exploration (UNE) with bilateral exploration (BNE).
Method: Between 1990 and 1995, 72 patients underwent initial neck exploration for primary hyperparathyroidism. There were 26 men and 46 women, with a mean age of 57·4 ± 12·5 years (range 21–80 years). Preoperative US was carried out by an experienced radiologist. Three surgeons adopted a policy of 'selective' US-guided UNE; the fourth surgeon performed routine BNE.

Results: Sixty-three of 72 patients had preoperative US. This was positive in 52 patients; of whom 27 underwent a UNE, 23 had a BNE, and two patients had a UNE converted to a BNE. Patients with 'negative' US ($n = 11$), and those receiving no preoperative localization test ($n = 9$) underwent BNE. The sensitivity, specificity and accuracy of US were 80 per cent (52 of 65), 100 per cent (61 of 61), and 90 per cent (113 of 126), respectively. Both surgical approaches were highly successful, with no significant difference [BNE: 97 per cent (33 of 34) vs US-guided UNE: 93 per cent (27 of 29), $P > 0\cdot05$)]; both incurring very low morbidity.
Conclusion: In the presence of an experienced radiologist US-guided UNE for sporadic primary hyperparathyroidism achieves comparable success rates as for BNE.

Endocrine/Transplantation 005

Starting a new clinical service — is a learning curve a necessity?

K.K. Madhavan, J.L.R. Forsythe and O.J. Garden *Scottish Liver Transplant Unit, Royal Infirmary Edinburgh, Edinburgh*

Background: A learning curve with gradual improvement in results and outcome is considered a necessary experience in the starting of any new clinical service. This study was aimed at testing this hypothesis in the context of the Scottish Liver Transplant Unit which has completed 5 years since inception.
Method: Over the last 5-year period, 163 patients underwent 182 orthotopic liver transplants (OLTs). These patients were studied with both peroperative and postoperative endpoints. Operation time and transfusion requirements as well as 30-day mortality was analysed year by year. Overall patient and graft survival, mortality in fulminant hepatic failure (FHF) transplants, incidence of hepatic artery thrombosis (HAT), primary non-function (PNF) and biliary complications were analysed year by year. Survival data were analysed using the Kaplan–Meir method and significance in survival difference analysed using the log-rank test ($P = < 0\cdot05$).
Results: Over the 5-year period, the overall patient and graft survival was 82 per cent (mean patient survival of 47·8 months) and 75 per cent (mean graft survival of 44 months), respectively. Both operating time and intraoperative blood transfusions showed gradual reduction over the years. The overall 30-day mortality and mortality for FHF transplants showed reduction. The incidence of PNF, HAT and biliary complications remained low through the period.

	1st year	2nd year	3rd year	4th year	5th year
Transplants	31	34	45	44	34
30-day deaths	5	3	6	4	1
% mortality	16	9	13	9	3
FHF deaths	1 (3)*	3 (5)*	1 (7)*	0 (7)*	0 (5)*
HATs**	1	0	1	1	0

*The values in brackets indicate the total number of OLTs for FHF for the year; **Only acute episodes during index admission are included.

Conclusion: Although a learning curve is not a must for a new clinical service and results can be good from the start, experience results in further improvement in various factors which may have an impact on overall results.

Endocrine/Transplantation 006

The role of nitric oxide in renal ischaemia reperfusion injury

S.C. Weight and M.L. Nicholson *University Department of Surgery, Leicester General Hospital, Leicester*

Background: This study investigated the role of nitric oxide (NO) in renal warm ischaemia reperfusion (WI/R) injury.
Method: Groups of rats underwent bilateral renal WI/R (15–45 min/20 or 80 min) prior to a left nephrectomy for analysis of renal NO (nitrate nitrite) and oxidative DNA damage (8-oxodG). The glomerular filtration rate (GFR) was measured (days 2 and 7) prior to killing for right kidney analysis and morphology. A further group received the NO synthase (NOS) inhibitor L-NAME (50 mg/kg intravenously) before WI.
Results: Following WI renal NO rose early and was maintained to day 7 whilst 8-oxodG peaked at 20 min. The decrease in the GFR was in line with the WI duration as was the morphological damage L-NAME reduced NO to day 7 with a simultaneous decrease in 8-oxodG at 20 mm but elevation at day 7. A deterioration in GFR but not morphology was evident.

	Nitric oxide (μM) reperfusion time		
WI group	20 min	80 min	Day 7
Control		442 (17)	426 (22)
15 min	762 (95)‡	865 (57)†	1110 (48)†
30 min	862 (44)†	1010 (142)†	1130 (60)†
45 min	997 (49)†	982 (54)†	1080 (29)†
L-NAME	562 (69)†		867 (75)‡

Results are mean (SEM); *$P \leq 0\cdot05$ vs control; †$P \leq 0\cdot01$ vs control; ‡$P \leq 0\cdot01$ vs control. The control for group L-NAME is WI group 45 min.

	8-oxodG (/10^5dG) reperfusion time			GFR (ml/min) reperfusion time	
WI group	20 min	80 min	Day 7	Day 2	Day 7
Control		2·0 (0·7)		2·5 (0·1)	2·5 (0·2)
15 min	6·7 (1·0)*	1·8 (0·5)	0·1 (0·01)	1·3 (0·2)	1·7 (0·2)
30 min	5·2 (1·7)*	2·6 (0·9)	4·1 (0·5)	0·8 (0·1)‡	1·4 (0·1)
45 min	14·6 (0·9)‡	3·5 (0·5)	2·0 (0·5)	0·6 (0·1)‡	1·2 (0·1)*
L-NAME	4·5 (0·8)†		2·9 (0·01)‡	0·3 (0·1)*	0·6 (0·1)‡

Results are mean (SEM); *$P \leq 0\cdot05$ vs control; †$P \leq 0\cdot01$ vs control; ‡$P \leq 0\cdot01$ vs control. The control for group L-NAME is WI group 45 min.

Conclusion: In recoverable renal WI/R injury NO increased early and remained elevated through to day 7. NOS inhibition ameliorated early renal damage but exacerbated the late injury suggesting the early burst of NO is cytotoxic but overall NO may exert a protective effect.

Endocrine/Transplantation 007

Kidney damage at organ retrieval — the facts

H.C.C. Pleass, R.K. Praseedom, F.M. Seeney and J.L.R. Forsythe
Scottish Liver and Renal Transplant Unit, Royal Infirmary of Edinburgh, Edinburgh

Background: This study aimed to determine the incidence, risk factors and outcome of kidney damage sustained at organ retrieval.
Method: Data were obtained from the UK Transplant Support Service Authority on all kidneys retrieved from cadaveric donors within the UK and Republic of Ireland, between January 1992 and December 1996. The incidence of damage reported at retrieval and at transplantation was recorded. In addition the outcome of the kidneys, whether used locally, exported or discarded was determined. Age of donor, the type of retrieval and the number and type of operating surgical teams involved were all recorded. Statistical analysis used Cox regression models fitted to renal allograft survival data.
Results: A total of 9014 kidneys were retrieved from cadaveric donors. Of these, 1726 (19 per cent) were reported as damaged, but only 78 were not transplanted because of the recorded retrieval injury. Of the transplanted kidneys, only 16·5 per cent were reported as damaged by both the donor and recipient centres. In multiorgan retrievals where the liver surgeon retrieved both liver and kidneys, the recorded renal injury rate was 16·8 per cent. Where liver and kidney teams were present at retrieval the injury rate was 21·2 per cent, compared with 26 per cent at kidney only retrievals. Kidneys retrieved and transplanted locally had a 14 per

cent incidence of injury, whereas those exported and transplanted elsewhere had a 30 per cent injury rate. The range of donor age was 0 to 76 years. Sixty-two per cent of damaged kidneys came from donors greater than 40 years of age. Donor age had a significant effect on both 1- and 3-year graft survival ($P = 0{\cdot}0001$) whereas kidney damage alone did not significantly affect 1- ($P = 0{\cdot}2$) or 3-year survival ($P = 0{\cdot}066$).

Conclusion: Kidney damage is both common, under-reported and more likely to occur in the elderly donor where only kidneys are retrieved by a renal team. Although this may reflect poorer surgical exposure or relative inexperience of the operating surgeon, damaged but transplantable kidneys tend to be exported and graft survival is not significantly affected.

Endocrine/Transplantation 008

Piggyback vs classical orthotopic liver transplantation, a retrospective analysis

H.C.C. Pleass, K.K. Madhavan, M. Akyol, J.L.R. Forsythe and O.J. Garden *Scottish Liver Transplantation Unit, Royal Infirmary of Edinburgh, Edinburgh*

Background: Piggyback orthotopic liver transplantation (PBOLT) has potential advantages over the classical technique (COLT), because it avoids the need for veno-venous bypass. The aim of this study was to compare these two surgical techniques in terms of transfusional requirements, morbidity and mortality.

Method: The results of a consecutive series of 66 PBOLT were compared with a previous cohort of 43 COLT. Data were obtained retrospectively from standard proforma. The indications for the PBOLT were chronic liver failure in 54, fulminant hepatic failure in six and six re-transplants. Although a temporary portocaval shunt was fashioned in 34 patients none required veno-venous bypass. Of the 43 COLT, 29 were for chronic liver failure, five for fulminant hepatic failure and nine re-transplants. All 43 utilized veno-venous bypass.

Results:

	Blood product transfused		
	Red blood cells	Fresh frozen plasma	Platelet
Piggyback ($n = 66$)	6·4 units	3·9 units	6·4 units
Classical ($n = 43$)	10·5 units	9·9 units	7·2 units

	Complications				
	Renal failure	Haemorrhage	Hepatic artery thrombosis	Venous outflow obstruction	30-day mortality
Piggyback	17 (25%)	3	4	2 (acute) 4 (chronic)	5
Classical	9 (21%)	3	3	0	3

Conclusion: Although the piggyback technique avoids the specific complications related to veno-venous bypass and has a reduction in the transfusional requirements, graft outflow obstruction remains a potential source of morbidity. A prospective randomized trial is required to determine the optimum surgical technique for adult OLT.

Endocrine/Transplantation 009

The spleen as a site for human islet autotransplantation

S.A. White, J.F. Birch, M. Forshaw, D. Power and A.R. Dennison
Department of Surgery, Leicester General Hospital, Leicester

Background: The spleen can be used as an alternative site to the liver for human islet autotransplantation (AT). Islets have been infused via the short gastric (SG) veins in an attempt to avoid splenic vein thrombosis and in cases where the splenic vein cannot be preserved during the pancreatectomy procedure. The aim of this study was to assess the anatomical variation of the SG veins.

Method: A total of 27 human cadavers were studied (12 male, 15 female) in order to assess splenic venous drainage.

Results: A total of 76 SG veins were identified. The median number was three (range 1 to 6). In over 80 per cent of cases there was a direct communication between the short gastric veins and the other draining veins of the spleen (i.e. splenic vein or left gastroepiploic [LGE] veins). Only SG vein 1 (80 per cent), 2 (26 per cent) and 3 (9 per cent) communicated directly into the splenic pulp the remainder communicating with the splenic vein (85 per cent) or the LGE (15 per cent).

Conclusion: This study suggests that during splenic islet AT via the SG veins there is great potential for reflux into the portal venous system. This could have dramatic consequences upon portal pressure and portal hypertension following a combined intra-portal and splenic islet AT due to reflux of 'splenic' islet tissue back into the portal vein.

UGI 001

Laparoscopic Nissen vs anterior fundoplication: a randomized trial

N. Davies, D.I. Watson, G.K. Pike, P.G. Devitt, R. Britten-Jones and G.G. Jamieson *The University Department of Surgery, Royal Adelaide Hospital, Adelaide, Australia*

Background: The aim of this study was to determine whether a laparoscopic anterior fundoplication is associated with a lower incidence of postoperative dysphagia than laparoscopic Nissen fundoplication, whilst still achieving a durable antireflux barrier. Initial outcomes are presented.
Method: One hundred and seven patients presenting for laparoscopic antireflux surgery were prospectively randomized to undergo either a Nissen fundoplication (53) or an anterior 180° hemifundoplication (54). Patients were blinded to which procedure had been performed. Clinical assessment was performed by a blinded independent investigator, who used multiple standardized clinical grading systems to assess the dysphagia, heartburn and patient satisfaction 1, 3 and 6 months following surgery. Objective measurement of lower oesophageal sphincter pressure, oesophageal emptying time, distal oesophageal acid exposure and endoscopic healing of oesophagitis was performed.
Results: Operating time was similar for the two procedures. Whilst resting and residual lower oesophageal sphincter pressures were lower (30 vs 17 and 15 vs 5) following anterior fundoplication, oesophageal emptying times (59 vs 54 s), acid exposure times and ability to heal oesophagitis were similar. At 3 months follow-up the clinical outcomes of postoperative dysphagia, relief of heartburn, and overall satisfaction were similar for the two procedures. At 6 months patients who had undergone an anterior fundoplication experienced less dysphagia and were more satisfied with their clinical outcome.
Conclusion: Laparoscopic anterior fundoplication achieved equivalent control of reflux and more physiological postoperative manometry parameters. It did not result in improvement in the measured clinical outcomes at 3 months but at 6 months there was less dysphagia.

UGI 002

The potential dangers of laparoscopic repair of perforated peptic ulcers

G.S.M. Robertson, S.A. Wemyss-Holden* and G.J. Maddern*
*Departments of Surgery, Leicester Royal Infirmary, Leicester and *The Queen Elizabeth Hospital, Woodville, South Australia 5011*

Background: The gains that accompany elective upper gastrointestinal laparoscopic surgery are particularly obvious. There is a tendency to assume this will apply to those with generalized peritonitis due to perforated peptic ulcers.
Method: This non-randomised concurrent cohort study compared 15 consecutive laparoscopic repairs of perforated peptic ulcers (Lap group) with a concurrent group of 15 consecutive open repairs (Open group).
Results: There were no differences preoperatively in age ($P=0{\cdot}32$), sex ($P=0{\cdot}31$), duration of perforation ($P=0{\cdot}73$), APACHE II score ($P=0{\cdot}27$), ASA grade ($P=0{\cdot}31$), or hourly urine output ($P=0{\cdot}09$) between the two groups. The mean duration of laparoscopic surgery was 77 min compared with 72 min with open repair ($P=0{\cdot}54$). One patient had a prepyloric ulcer, the rest were anterior or superior duodenal ulcers. A median of two sutures were used (range 2–4) to secure the omental patch. Laparoscopic lavage used a mean of 5·5 L compared with 4·0 L ($P=0{\cdot}03$), there were three conversions. ITU care was required in three patients in the Lap group (two with renal failure) and two patients in the Open group (no renal failure). One patient in each group died. Postoperatively the duration of nasogastric drainage, intravenous fluid administration and time to oral fluids and diet showed no differences in gastrointestinal tract recovery. The median duration of stay of 6 days in the Lap group did not differ from the 7 days in the Open group.
Conclusion: This comparison provides anecdotal evidence that the pathophysiological insult of laparoscopy in the setting of generalized peritonitis might increase the perioperative risk of organ failure particularly renal and provides a mandate for a prospective randomized controlled trial.

UGI 003

Scanning laser doppler flowmetry and intra-luminal recirculating gas tonometry in the assessment of gastric perfusion during oesophageal resection

N.H. Boyle, W.J. Owen, A.C. Pearce and R.C. Mason *United Medical and Dental School, Guy's and St Thomas' Hospitals, London*

Background: Of the aetiological factors associated with leak and benign stricturing of the anastomosis following oesophageal resection and reconstitution of gastrointestinal continuity with a gastric tube, ischaemia caused by poor perfusion at the gastric end of the anastomosis is thought to be important. Scanning laser Doppler flowmetry (which creates a perfusion image) and continuously recirculating gas tonometry are new techniques that can assess changes in tissue perfusion and in this study, their ability to detect changes in gastric perfusion during oesophageal resection and formation of gastric tubes was assessed.
Method: Sixteen patients undergoing oesophageal resection for malignancy were studied. Tonometer balloons were placed in the stomach and proximal jejunum (alongside a feeding jejunostomy feeding catheter). Measurements of gastric and jejunal intra-mucosal pHi and a laser Doppler scan of the stomach were made at three time points: prior to gastric mobilization, after division of left gastric, short gastric and left gastroepiploic vessels and finally after formation of the gastric tube. In each subject, from a grey-scale photographic image of the stomach produced by the scanning laser, identical regions of interest (ROIs) each of $1{\cdot}5\,\text{cm}^2$ were interrogated from each scan, these representing the area of anastomosis, the gastric corpus and the antrum. Mean perfusion units (PUs) from the 1750 individual measurements taken within the ROI were then calculated for each of these areas. Mean measurements for the whole stomach or gastric tube were also made.
Results: There were significant falls in perfusion measured with the scanning laser Doppler in all the subjects between each time point and in all areas of the stomach. Mean perfusion of the stomach was 530 PUs prior to mobilization and this fell to 313 PUs after mobilization representing a mean fall of 40 per cent. There was a gradient of reduced perfusion between the antrum (fall 25 per cent, $P<0{\cdot}05$) and the area used for the anastomosis in the fundus (mean fall 56 per cent, $P<0{\cdot}001$). After formation of the gastric tube, mean perfusion at the anastomosis site fell to a mean of 197 PUs (mean fall 61 per cent, $P<0{\cdot}0005$). Prior to mobilization mean gastric and jejunal pHi were 7·37 and 7·46, respectively. These figures changed to 7·18 and 7·36, respectively after mobilization and to 7·29 and 7·38 after anastomosis formation.
Conclusion: This study confirms our pilot study that both these techniques can be used intra-operatively to assess changes in gastric perfusion during oesophagectomy and we have observed significant falls in perfusion in that area of the stomach used for the gastro-oesophageal anastomosis between the start and end of surgery. Further study is needed to assess if these methods can be used to predict ischaemia-related anastomotic complications.

UGI 004

Efficacy and incidence of post-fundoplication symptoms at a median of 5 years following open Watson fundoplication

K.L. Campbell and A. Munro *Raigmore Hospital, Inverness and Aberdeen Royal Infirmary, Foresterhill, Aberdeen*

Background: While ease of performance laparoscopically has encouraged dissemination of the Watson partial wrap fundoplication, independent assessment of its claims to provide effective relief of reflux symptoms with a lower incidence of super-competence type symptoms remains lacking. The aim of this study was to establish the long-term efficacy and incidence of post-fundoplication symptoms from an independent experience with the open Watson fundoplication.
Method: Data from 49 patients having undergone an open Watson fundoplication over an 8-year period were reviewed and patients were interviewed to establish their current DeMeester Symptom Score for reflux and the incidence of post-fundoplication symptoms. A Visick grading was determined separately in each case. The Paired Wilcoxon Rank Sum Test was used for statistical comparisons.
Results: Oesophagitis was noted endoscopically in 67 per cent with 92 per cent having DeMeester symptom scores of ≥4. Pre-operative 24-h pH studies (performed in 85 per cent of cases) documented a median of 12·5 per cent time spent at pH <4 when supine, a median of 14 reflux episodes >5 min and a median composite DeMeester score of 85. Post-operative studies (in 53 per cent of cases) yielded equivalent values of 0, 1 and 14 respectively (all $P<0{\cdot}01$). Follow-up interviews were completed in 42 (86 per cent) at a median interval of 5 years (range 1–9 years). The DeMeester symptom score was 1 or less in 86 per cent ($P<0{\cdot}001$). On direct questioning failure of eructation was noted in one (2·4 per cent) and inability to vomit in six (14·3 per cent). No symptoms at all were elicited in 66·7 per cent (Visick I), mild symptoms in only 26·1 per cent (Visick II), while 4·8 per cent required treatment but were controlled (Visick III) and 2·4 per cent were not fully controlled.
Conclusion: These data suggest that the Watson fundoplication gives satisfactory control of reflux with a low incidence of post-fundoplication symptoms and a very high rate of overall patient satisfaction in the medium to long term. Similar results may be anticipated in laparoscopic Watson fundoplication.

UGI 005

Oesophago-gastric junction cancer is related to alcohol consumption but not smoking

J.P. Byrne*, J. Mathers†, J. Parry†, C.B.J. Woodman† and S.E.A. Attwood* **University Department of Surgery, Hope Hospital, and †Centre for Cancer Epidemiology, University of Manchester, Christie Hospital NHS Trust, Withington, Manchester*

Background: The aim of this study was to identify any association between tobacco and/or alcohol consumption and cancers involving the oesophago-gastric junction, compared with those confined either to the oesophagus or stomach. Any association with subsite was defined by comparing age at diagnosis in those who consume tobacco/alcohol with those that did not.
Method: Fourteen hundred cases of cancer of the oesophagus or stomach in 1993 were identified from the North Western Regional Cancer Registry (population 4,030,800). Case-note review identified 1067 new diagnoses of oesophageal or gastric cancer. Tumour site was recorded as involving the oesophago-gastric junction, or oesophagus/stomach alone. Consumption of cigarettes and alcohol were recorded from the notes. Smokers were compared with non-smokers. Those consuming more than 5 units of alcohol per week were compared with those who did not.
Results: Three hundred and thirty-two cancers involved the oesophago-gastric junction, 281 were confined to the oesophagus, and 454 to the stomach. Three hundred and sixty-one (54·1 per cent) men and 120 (27·3 per cent) women had smoked. Smokers of both sexes developed carcinoma of the oesophagus and stomach at a significantly younger age than non-smokers, whereas there was no such difference for cancers of the oesophago-gastric junction. One hundred and twenty-nine (19·3 per cent) men and 14 (3·2 per cent) women consumed more than 5 units of alcohol per week. Consumption of more than 5 units of alcohol per week was associated with significantly younger age at diagnosis in men for cancers at all sites.

	Oesophagus		Oesophago-gastric junction		Stomach	
Median age (years)	Male	Female	Male	Female	Male	Female
Non-smokers/drinkers	71·2	76·6	68·1	72·4	75·5	77·6
Smokers	64·9**	68·5**	66·6	67·7	69·6**	69·2**
>5 units/week	59·8**	—	63·3*	—	68·0*	—

*$P<0{\cdot}05$; **$P<0{\cdot}01$.

Conclusion: Cancer involving the oesophago-gastric junction represents an epidemiologically distinct disease entity, associated with male sex and younger age at diagnosis compared with cancers confined to the oesophagus and stomach. Oesophago-gastric junction cancer and alocohol consumption are associated with different age at diagnosis, whereas smoking is not, unlike cancer confined to the oesophagus or stomach.

UGI 006

Peritoneal fluid cytology in the staging of oesophageal and gastric malignancies

K.K. Singh, D. Caesar, G. Low, A.R.W. Williams and S. Paterson-Brown *University Department of Surgery, Royal Infirmary of Edinburgh, Edinburgh*

Background: The aim of this study was to examine the role of peritoneal fluid cytology in laparoscopic staging of oesophageal and gastric malignancies.
Method: Data were audited prospectively for 125 patients with gastro-oesophageal malignancy who were assessed and staged in a specialist unit. Laparoscopy was carried out in 71 (57 per cent) patients (26 oesophageal and 45 gastric; median age 67 years). Saline instilled into the peritoneal cavity was aspirated and sent for cytology. Ascites, if present, was sampled separately. Fluid for cytology was obtained in 56 (79 per cent) patients.
Results: Early (TNM stage I and II) disease was present in 13 (18 per cent) of the patients who were staged with laparoscopy. Stage III disease was present in 28 (39 per cent) of the patients while the remaining 30 (42 per cent) had advanced stage IV disease. After staging curative or palliative resection of the tumour was carried out in 47 (66 per cent) of the patients. Peritoneal fluid aspirate was positive for malignant cells in 11 (19·6 per cent) and negative for 45 (80·4 per cent). There were no cases of positive cytology in stage I and stage II disease. Positive results were obtained in two (9 per cent) of the 22 patients with stage III disease and in nine (36 per cent) of the 25 patients with stage IV disease. There was a significant correlation between positive cytology and stage IV disease (χ^2 $P=0{\cdot}0007$). Median survival for stage III and stage IV disease was 31·3 months and 5·1 months, respectively (log rank $P<0{\cdot}00001$).
Conclusion: While positive peritoneal cytology is indicative of advanced disease, in 64 per cent of the patients with stage IV disease the peritoneal aspirate did not yield any malignant cells. Routine peritoneal fluid cytology does not offer any significant contribution to the staging of gastro-oesophageal cancers.

UGI 007

An audit of treatment of cancer of the oesophagus in a district general hospital

R.G. Nair, P.N. Foster and A.R. Quayle *Macclesfield District General Hospital, Macclesfield*

Background: The aim of this study was to audit the treatment of cancer of the oesophagus in a District General Hospital, and to compare results with regional and national audit studies.
Method: The treatment of 132 proven cases of cancer of the oesophagus seen between January 1990 and October 1997 was reviewed. All patients were under the care of the same Consultant surgeon (ARQ). Patients were identified from the computerized patient administration system, which was cross-checked with pathology records and operating theatre registers. The results were compared with those in a series from Leeds and a national audit study.
Results: Of 132 patients, 86 were male and 46 were female. The lesion was in the upper oesophagus in seven, middle in 30 and lower in 95 patients. Histology, available in 131/132 cases revealed adenocarcinoma in 84 squamous cell carcinoma in 44 and other neoplasms in three. Metastases at diagnosis were identified in 24/132 patients. Surgery was performed in 52/132 patients — resectional procedures in 37 (17 Ivor Lewis, 11 cardio-oesophagectomies, seven transhiatal oesophagectomies in two three-stage procedures) and palliative surgical intubation in 15. Therapeutic endoscopic procedures were performed in 50 patients — dilatation in 21, Atkinson tube insertion in 22, laser therapy in two and wall stent insertion in five. Radiotherapy was given to 37 patients — curative in eight and palliative in 29. Fourteen patients received a combination of two or more treatment modalities. The complication rate among surgically treated patients was 40 per cent and the 30-day hospital mortality rate was 11·5 per cent compared to 14 per cent in a survey of 50 UK specialist thoracic centres. The median survival for all patients was 6 months — broken down as 9 months for surgically treated cases, 6 months in endoscopically treated cases and 6 months for those receiving radiotherapy.
Conclusion: This series has demonstrated a preponderance of male patients, and those with adenocarcinoma of the lower oesophagus, the latter finding mirroring recent trends in the West. Morbidity and mortality figures in Macclesfield compare favourably with those seen in regional and national audit studies.

UGI 008

The pattern of recurrence of adenocarcinoma of the oesophago-gastric junction

J. Wayman, D. Craig, N. Hayes, S.A. Raimes and S.M. Griffin
The Oesophago-Gastric Cancer Unit, Newcastle General Hospital, Newcastle upon Tyne

Background: Previous reports have suggested that 80 per cent of gastric cancer recurrences are with peritoneal disease. The aim of this study is to examine whether tumours of the oesophago-gastric junction conform to this pattern of recurrence or exhibit a distinct natural history.
Method: The follow-up of patients with adenocarcinoma of the lower oesophagus and gastric cardia who had undergone surgery with curative intent since 1991 was examined for evidence of recurrent malignant disease. Clinical evaluation was supported by ultrasound, computerized tomography, radio-isotope bone scan, endoscopy and laparotomy each with biopsy and histology where appropriate. Patients in whom the diagnosis of recurrent disease was unsupported other than by clinical impression were excluded. Statistical analysis was by the χ^2-squared and Mann–Whitney U-tests.
Results: One hundred and twenty-two patients with oesophago-gastric junction tumours (53 gastric cardia (IGCA* Type 2)) and 69 adenocarcinomas of the lower oesophagus (IGCA Type 1) have been followed up for a median of 19 (1–84) months. There was a similar sex and age distribution for Type 1 and Type 2 junctional adenocarcinomas (male:female 3·4:1 vs 6·6:1; age 63 (40–77) vs 70 (42–78). Forty-one patients developed proven recurrent disease. The median time to recurrence was 7 (1–28) months and was similar between Types 1 and 2 subgroups. The median time to death thereafter was 2 (1–15) months. Only three cases of peritoneal dissemination were found among the 17 Type 2 junctional cancer recurrences and only 1/24 among the Type 1 group. The most frequent mode of dissemination for both groups was haematogenous spread (14/24 of Type 1 and 10/17 of Type 2 recurrences). Haematogenous dissemination accounted for a significantly greater proportion especially of first-year failures (12/15 vs 11/26; $P<0{\cdot}05$). The most frequent sites of haematogenous spread were to liver (9), bone (10), brain (3) and lung (3). Local lymph node recurrence occurred in 6/24 cases of Type 1 and 4/17 Type 2 tumour recurrences, most frequently to coeliac or porta hepatic nodes (7/10). Local recurrence occurred in 7/24 and 8/17 cases, respectively. Disease-free survival correlated inversely with lymphatic ($P<0{\cdot}001$), and neural ($P=0{\cdot}002$) invasion and lymph node positivity ($P<0{\cdot}001$).
Conclusion: The natural history of cardial tumour recurrence is similar to that of adenocarcinoma of the lower oesophagus and differs from more distal gastric cancers. Recurrence of these oesophago-gastric junction tumours is by haematogenous and lymphatic rather than transcoelomic spread. This finding has implications for the choice of route of administration of adjuvant therapy for junctional compared with other gastric tumours.

---

*International Gastric Cancer Association classification.

UGI 009

Clinical and endoscopic response to neoadjuvant therapy for carcinoma of the oesophagus

D.J. Bowrey, G.W.B. Clark, S.A. Roberts, T.S. Maughan*, A.B. Hawthorne and P.D. Carey *Department of Surgery, University Hospital of Wales, and *Department of Clinical Oncology, Velindre Hospital, Cardiff*

Background: Recent evidence indicates that neoadjuvant therapy confers a survival advantage to patients with oesophageal cancer. Local tumour response to neoadjuvant therapy was evaluated by clinical, endoluminal ultrasound (EUS) and histopathological criteria in patients with carcinoma of the oesophagus.
Method: Sixteen patients with oesophageal cancer, adenocarcinoma ($n=11$), squamous carcinoma ($n=5$) were studied prospectively. Patients underwent clinical assessment and EUS pre- and post-neoadjuvant therapy. Dysphagia was scored on a scale of 1 to 4. Twelve patients received radiotherapy (40 Gy) and two cycles of cisplatin/5-FU, whilst four patients with distal tumour extension received four cycles of epirubicin, cisplatin and 5-FU. Twelve patients underwent oesophagectomy on completion of neoadjuvant therapy.
Results: Tumour depth determined by EUS was significantly reduced following treatment. EUS did not demonstrate a reduction in T-stage for any patient, while three patients were down-staged from N1 to N0. The effects of treatment are summarized in the tables below.

EUS findings	Before	After
Depth (mm)	12·4 ± 1·7	9·1 ± 0·9*
Length (cm)	6·2 ± 1·1	4·9 ± 0·8

*$P<0{\cdot}05$ paired *t*-test.

Response	Adenocarcinoma	Squamous carcinoma
↓ Dysphagia score	2/11 (18%)	4/5 (80%)*
Tumour depth before/after	1·0 (IQR 0·8–1·4)	2·5 (1·1–3·6)**
100% pathological response	0/7 (0%)	3/5 (60%)*

*$P<0{\cdot}05$ Fisher's exact test, **$P<0{\cdot}05$ Mann–Whitney U-test.

Two patients with adenocarcinoma had progression of nodal disease during therapy.
Conclusion: EUS did not detect tumour regression according to T-stage, possibly due to an inability to differentiate tumour from post-treatment fibrosis, rather, serial EUS assessment of tumour depth may prove to be useful in determining the response to therapy. Based on clinical assessment, EUS and histopathology, patients with oesophageal squamous carcinoma responded favourably to neoadjuvant therapy, while such a response was infrequent in patients with adenocarcinoma.

H & P 001

Audit of surgical management of liver trauma: a single-unit experience

J.A. Paraskevopoulos, S. Samoilis, G. Papadakis, S Kalimeris, O. Kostopoulos and A. Ioannides *First Department of General Surgery, 'KAT' General Hospital for Accidents, Athens, Greece*

Background: The aim of this study was to provide a retrospective audit of the surgical management of patients with liver trauma.
Method: We studied 46 consecutive patients (36 male, 10 female) with a median age of 43 years (range 21–67) who were transferred to our Department after sustaining a blunt abdominal trauma ($n=44$) or a penetrating injury ($n=2$) between 1994 and 1996. On admission, all patients were haemodynamically unstable. After successful resuscitation a diagnosis of intra-abdominal bleeding was made using peritoneal lavage. Subsequently, emergency laparotomy revealed liver trauma in all cases classified according to the Liver Injury Scale (Grades I–V).
Results: Grade I ($n=17$), II ($n=16$), III ($n=11$) and V ($n=2$), respectively. Associated injuries included splenic rupture ($n=15$), gallbladder avulsion ($n=5$), inferior vena cava laceration ($n=3$), shattered kidney ($n=4$) and miscellaneous ($n=17$). Various procedures were carried out for control of liver bleeding as follows: topical haemostasis ($n=17$), hepatorrhaphy by the finger fracture technique plus omentoplasty ($n=3$), deep liver suturing with omentoplasty ($n=22$) and resectional debridement ($n=4$). Splenectomy ($n=15$), cholecystectomy ($n=4$), nephrectomy ($n=4$), small bowel resection ($n=1$) and suture of various lacerations ($n=5$) were also performed at the same time. Complications developed in 10 (21·7 per cent) patients whilst the overall mortality was 8·7 per cent (four patients).
Conclusion: Proper and experienced management of liver trauma in a well-organized trauma centre results in a reasonable complication rate with acceptable mortality.

H & P 002

How and where should blunt liver trauma be managed?

U Gur, S. Bramhall, M. Dolapci, I.M. Bain, P. McMaster, D.A.J. Mayer and J.A.C. Buckels *The Liver Unit, Queen Elizabeth Hospital, Birmingham*

Background: There has been an increasing trend for non-operative management of liver trauma. We report 34 tertiary referral cases of severe liver injury transferred to the Liver Unit in the last 6 years.
Method: Thirty-four patients with blunt trauma were treated, of which 12 (35 per cent) were managed conservatively. Twelve of the 15 patients who had undergone surgery elsewhere required reoperation and a further seven underwent initial surgery in the Liver Unit. Nine major hepatic resections were performed, the remainder either had liver packs removal or haemostatic suturing.
Results: The overall mortality was eight patients (25 per cent), of which five had major anatomical resections, the other three liver packing alone. Four of the patients who died had other intra-abdominal injuries, two pancreatic and two splenic. The mean hospital stay for the operative group was 20 days. All patients treated conservatively made a good recovery, mean hospital stay was 12 days.
Conclusion: Conservative management of major blunt liver trauma is a safe and justified treatment modality, provided that the initial assessment of the patient is done appropriately. Treatment must be performed in specialized units where extensive surgical procedures can be offered. We recommend that patients with blunt abdominal trauma admitted to district general hospitals undergo contrast enhanced computed tomography (CT) scan prior to surgical treatment, several patients had delayed surgery at the admitting hospital without CT imaging — had this been done we believe these patients would have been referred immediately without initial exploration.

H & P 003

Phase I study of early nasogastric feeding in severe acute pancreatitis

F C. Eatock, A. Steven, C W. Imrie and C.R. Carter *Department of Upper Gastrointestinal and Pancreato-biliary Surgery, Glasgow Royal Infirmary, Glasgow*

Background: Recent work has suggested that enteral feeding may reduce the inflammatory response in severe acute pancreatitis, however, the placement of nasojejunal tubes in such patients carries risk from the need to transfer critically ill patients for X-ray screening or fibreoptic endoscopy. We undertook a Phase I study to assess the safety of nasogastric feeding in patients with severe acute pancreatitis.
Method: Twenty-six consecutive patients admitted to our unit with severe acute pancreatitis received feeding via nasogastric tube within 48 h of arrival. Severity of disease was defined by Glasgow Prognostic Criteria, APACHE II Score, C-reactive protein and contrast-enhanced computed tomography scan. All patients received full supportive care with cardioventilatory and renal support as required.
Results: Aetiology was identified as cholelithiasis (18 patients); ethanol (five) and miscellaneous (three). Median Glasgow Score was 5 (range 2–7); APACHE II Score 10 (4–28) and C-reactive protein 240 mg/L (79–385). Sixteen patients had significant pancreatic and peripancreatic necrosis. Eighteen patients underwent ERCP, six necrosectomy for infected necrosis or failure to improve and four internal drainage of pseudocyst. Eleven patients required ventilatory support, six of whom also required inotropic support with three also having renal dialysis. There were two deaths. The feed was well-tolerated in all but four patients. There was no evidence of recurrence of abdominal pain nor a secondary rise in C-reactive protein concentration on commencement of feeding.
Conclusion: We conclude that early nasogastric feeding in severe acute pancreatitis appears to be safe, well tolerated and worthy of further study.

H & P 004

A policy of urgent laparoscopic cholecystectomy for acute gallstone-related symptoms

G.S.M. Robertson, S.A Wemyss-Holden and G.J. Maddern
Department of Surgery, The Queen Elizabeth Hospital, Woodville, South Australia 5011

Background: Although the merits of urgent cholecystectomy for acute gallstone-related symptoms have been debated for decades, in the UK, particularly in the laparoscopic era, logistics have limited its assessment.
Methods: This study prospectively evaluated a policy of urgent laparoscopic cholecystectomy in all patients admitted as emergencies ($n=51$) over a 9-month period to a single surgical unit with acute cholecystitis (22), empyema of the gallbladder (8), biliary colic (15), pancreatitis (three) or jaundice (three). The results were audited and compared with those referred electively ($n=88$).
Results: There were no preoperative differences between the acute and elective groups in age (mean 51·6 vs 53·1, $P=0{\cdot}66$), sex (31 female vs 63, $P=0{\cdot}19$), body mass index (mean 27·8 vs 29·8, $P=0{\cdot}076$) or ASA grade >2 (11 vs 9, $P=0{\cdot}066$). Preoperative ultrasonography ($P=0{\cdot}0001$)

and liver function tests ($P=0{\cdot}0002$) were significantly different. Surgery in the acute group took significantly longer (mean 79 vs 64 min, $P=0{\cdot}0022$), involved more modifications in surgical technique ($P=0{\cdot}0007$) and accounted for all three conversions ($P=0{\cdot}021$) suggesting an increased difficulty. There were no deaths or reoperations. One cystic duct leak occurred requiring endoscopic stenting. Median hospital stay in the acute group was 4 days and in the elective group 2 days ($P<0{\cdot}0001$). Postoperative stay was also longer (median of two nights compared with 1 night, $P=0{\cdot}0004$).
Conclusion: The results suggest that a policy of urgent laparoscopic cholecystectomy by experienced surgeons in all patients admitted with acute symptoms can be carried out safely with minimal morbidity and economic and social advantages which make it the management of choice.

H & P 005

Magnetic resonance cholangiography reduces the need for ERCP prior to laparoscopic cholecystectomy

S. Dwerryhouse, E. Brown* and M. Vipond *Departments of Surgery and *Radiology, Gloucestershire Royal Hospital, Gloucester*

Background: With the advent of laparoscopic cholecystectomy many surgeons have adopted a policy of selective pre-operative endoscopic retrograde cholangiopancreatography (ERCP) for patients with risk factors for common bile duct (CBD) stones. As ERCP is invasive with a well documented morbidity we have evaluated magnetic resonance cholangiography (MRC) to detect CBD stones prior to laparoscopic cholecystectomy.
Method: All patients scheduled for operation for symptomatic gallstones underwent MRC if they had one or more risk factors for CBD stones: dilated CBD >7 mm on ultrasound, previous documented jaundice or pancreatitis, previous or current abnormal liver function tests. Patients then underwent ERCP within 1 week; if ERCP failed peroperative cholangiography was performed.
Results: Over a 20-month period, 37 patients were studied. Two patients failed to complete MRC because of claustrophobia. ERCP was unsuccessful in four patients. MRC identified six of seven patients found to have CBD stones. Two patients were incorrectly diagnosed with CBD stones by MRC. In this study MRC had a sensitivity of 86 per cent, specificity of 93 per cent, positive predictive value of 75 per cent and negative predictive value of 96 per cent.
Conclusion: MRC is a simple non-invasive method for pre-operative screening for CBD stones. In this study it would have reduced the need for ERCP by three-quarters.

H & P 006

Management of intrahepatic stone disease with a subparietal hepaticojejunal access loop

I.J. Beckingham*, J.E.J. Krige, P.C. Bornman and J. Terblanche
Department of Surgery, Nottingham, and Surgical Gastroenterology and Department of Surgery, University of Cape Town & Groote Schuur Hospital, South Africa*

Background: Intrahepatic stone disease (IHSD) presents difficulties in management because of recurrent stone and stricture formation and the difficulty of stone removal from within the intrahepatic ducts. We report our experience with the management of this condition after surgical removal of stones and formation of a subparietal hepaticojejunal access loop to allow postoperative percutaneous radiological access for stone removal and stricture dilatation.
Method: Between 1985 and 1997, 21 patients, mean age 34 years (range 24–66 years); 10 male and 11 female with IHSD have undergone surgery and formation of a hepaticojejunal access loop. Patients were followed prospectively and details of the number and type of procedures performed, stone clearance rates, morbidity and subsequent outcome were recorded.
Results: The distribution of stones within the liver was predominantly left-sided. Left lobe was the site of disease in 67 per cent (14/21) the right lobe in one (5 per cent) and bilateral disease in 28 per cent (6/21). There was associated atrophy of the left lobe in six patients who underwent additional left lateral segmentectomy at the initial operation. Following surgery, access loops were used for stone removal or stricture dilatation 97 times, median of four (range 0–25) procedures per patient. Complete stone clearance was achieved in 86 per cent (18/21) of patients with partial clearance in the remaining three. Stones were removed and crushed using a basket, snare or balloon and strictures dilated with a balloon. Access via the loop failed on only two occasions. Patients received parenteral antibiotics for 24 h after the procedure. There were no major complications and no mortality associated with the procedures.
Conclusion: The sub-parietal access loop permits long-term access to the biliary system allowing removal of stones and dilatation of strictures in IHSD with low morbidity.

H & P 007

Lessons learnt from day-case laparoscopic cholecystectomy

J.A. Grabham, A. Knight, D. Raitt and W.W. Barrie *Leicester General Hospital, Leicester*

Background: Day-case laparoscopic cholecystectomy has failed to become popular in the UK due to concerns about safety and patient tolerance. We have audited our early experience of the procedure in an attempt to identify and address any problems.
Method: A case-note review was performed of all patients who underwent attempted day-case laparoscopic cholecystectomy between January 1995 and May 1997, supplemented by a postal questionnaire.
Results: During the 28-month period, 50 patients underwent attempted day-case laparoscopic cholecystectomy. Their mean age was 50 years (range 21–57 years) and 46 were female. All were either ASA I or II. The mean operating time was 80 min (range 40–190 min). Sixteen patients (32 per cent) required overnight admission. The most common reasons for admission were postoperative nausea and vomiting (nine patients) and abdominal pain (five patients). One patient was readmitted 4 days after surgery with jaundice from a retained stone in the common bile duct and was successfully treated by endoscopic sphincterotomy. Two patients developed umbilical wound infections which settled on oral antibiotics. Sixty per cent of patients responded to the questionnaire. Of those who had been successfully treated as day-cases, 18 per cent described significant postoperative nausea and vomiting with 82 per cent experiencing significant abdominal pain during the first 24 h after discharge. The majority (82 per cent) were happy to have been managed as day-cases but three would have preferred overnight admission.
Conclusion: Day-case laparoscopic cholecystectomy can be safely performed in a British day surgery unit but approximately one third of patients may require overnight admission, largely due to nausea and abdominal pain. These symptoms are also common after successful same-day discharge and additional measures must be taken to address these problems.

H & P 008

The need for a pre-operative ERCP predicts difficult laparoscopic cholecystectomy

C.V.N. Cheruvu, S. Singh, J. Mathew, M. Uheba and I.M. Paterson *Frimley Park Hospital, Frimley, Surrey*

Background: Minimal access surgery and ERCP have made invaluable contributions to the management of patients with biliary stone disease.

The aim of this study was to confirm a clinical suspicion that the need for preoperative ERCP would predict difficult laparoscopic cholecystectomy (LC).

Method: A consecutive series of 70 patients who had an ERCP and a subsequent LC between December 1992 and December 1996 were analysed. The variables studied included conversion rates, operative time, operative difficulty, duration of hospital stay, analgesic requirement and complications. An age- and sex-matched control group of 134 patients who had LC without preoperative ERCP were identified. This group were also matched for the date of the operation in keeping with the learning curve.

Results: The study group comprised 26 (37 per cent) males and 44 (63 per cent) females with a mean age of 58·5 years and the control group was well matched. In both groups 73 per cent of the operations were performed by a single consultant surgeon. A mean operative time of 76·5 min and 54·5 min were recorded for the study and the control groups, respectively ($P<0\cdot0001$). Operative difficulty was noted in 58·5 per cent compared with only 24 per cent of the control group. The conversion rates were 17 per cent and 6·8 per cent in the study and control groups, respectively. The mean postoperative stay was 4·3 days (range 1–48 days) compared with 2·16 days (1–13 days) in the control group ($P<0\cdot003$). The analgesic requirement was found to be significantly higher in the study group.

Conclusion: This study clearly shows that patients with biliary tract disease who required preoperative ERCP had more difficult laparoscopic cholecystectomies together with increased conversion rates, operating times, postoperative hospital stay, complication rates and analgesic requirements. Preoperative identification of a difficult LC would enable one to institute a safe management plan.

H & P 009

Management of primary hepatocellular carcinoma in a specialist hepatobiliary centre

K.K. Singh, S.J. Wigmore, E. Currie, K.K. Madhavan,
D.N. Redhead and O.J. Garden *University Department of Surgery, Royal Infirmary of Edinburgh, Edinburgh*

Background: The aim of this study was to assess the management and outcome of patients presenting with hepatocellular carcinoma at a tertiary referral centre.

Method: One hundred and seven consecutive patients (male 69 per cent, median age 62 years) with the diagnosis of hepatocellular carcinoma were audited prospectively between 1988 and 1997. Patients were clinically assessed and staged with computed tomography scan, ultrasound, angiogram, and laparoscopy with intraoperative ultrasonography.

Results: Following assessment, 34 patients (32 per cent) were considered unsuitable for any intervention, 56 patients (52 per cent) underwent chemo-embolization and 17 (16 per cent) underwent resectional surgery. There was one postoperative death in a cirrhotic patient (mortality 5·8 per cent). The median survival for these patients was 40·7 months (95 per cent CI range = 19·7–61·6). The overall 5-year survival for all patients was 6 per cent. At 2 years from diagnosis, marked differences were observed in the survival, with estimates of 83 per cent for resections, 23 per cent for chemo-embolization and 11 per cent for those who had no treatment (log rank $P<0\cdot00001$). Elevation of serum gamma glutamyl transferase ($R=0\cdot2$, $P<0\cdot03$) and alkaline phosphatase ($R=0\cdot2$, $P<0\cdot03$); presence of vascular invasion ($R=0\cdot3$, $P<0\cdot009$), presence of distant metastases ($R=0\cdot2$, $P<0\cdot05$), and increasing number of hepatic segments involved by tumour ($R=0\cdot2$, $P<0\cdot05$), correlated with poor survival.

Conclusion: Resectability of hepatocellular carcinoma remains low at 16 per cent and the overall survival is poor. It is important, however, that these patients are assessed and staged by a specialist surgical hepatobiliary unit and appropriate treatment modality is employed as this may result in a significant survival benefit for some patients.

Coloproctology 001

Randomized controlled trial of metronidazole to reduce pain after day-case haemorrhoidectomy

E.A. Carapeti, M.A. Kamm, P.J. McDonald and R.K.S. Phillips
Department of Surgery, St Mark's Hospital, Harrow, Middlesex

Background: The aim of this study was to investigate the effect of metronidazole on postoperative pain after day-case haemorrhoidectomy (DCH).
Method: Forty consecutive patients (17 male) aged 36–65 years (mean 49) randomly received metronidazole ($n=20$) or placebo in a double-blind manner. All received lactulose 2 days preoperatively. Diathermy haemorrhoidectomy was performed with no anal canal dressing. Patients were discharged on the same day and given diclofenac, 0·2 per cent glycerine trinitrate ointment, lactulose, a contact bleep number, and early outpatient review. Additional analgesics were used as required and patients completed questionnaires for pain, expectation of pain and satisfaction.
Results: Overall, patients experienced less pain than expected, except on days 3 and 4. Patients using metronidazole had significantly less pain on days 5, 6 and 7 compared to placebo ($P<0{\cdot}01$, $P=0{\cdot}02$ and $P<0{\cdot}01$). Nine patients on metronidazole used additional analgesia compared to 13 on placebo ($P=0{\cdot}34$). Return to work was significantly earlier ($P=0{\cdot}01$) with metronidazole (15 days) compared to placebo (18 days). There were two re-admissions (both on placebo), one for faecal impaction, the other secondary haemorrhage. Patient satisfaction was higher in the metronidazole group at weeks 1 ($P=0{\cdot}005$), and 6 ($P=0{\cdot}06$).
Conclusion: Prophylactic metronidazole assists DCH by suppressing secondary pain around days 5 to 7 leading to high patient satisfaction and earlier return to work.

Coloproctology 002

Proinflammatory effects of colitic mucosa on neutrophil adhesion

I.E. Nichol, S.M. Plusa, C. Marshall, J. Kirby, B.K. Shenton and J.S. Varma *Department of Surgery, University of Newcastle upon Tyne, Newcastle upon Tyne*

Background: To investigate the functional effects of inflammatory mediators produced by mucosal biopsies from patients with ulcerative colitis on neutrophil–endothelial interactions.
Method: Conditioned medium (CM) from incubated colitic and control mucosal biopsies was added to whole blood from a healthy donor. Expression of the neutrophil adhesion receptor CD11b and neutrophil-endothelial adhesion was determined by flow cytometry.
Results: Incubation with colitic CM produced significantly greater CD11b expression after 5 ($P=0{\cdot}004$), 15 ($P=0{\cdot}024$) and 30 min ($P=0{\cdot}025$) than controls. Neutrophil–endothelial adhesion ratio was significantly greater with colitic biopsies than controls ($P=0{\cdot}0052$).
Conclusion: Mucosal biopsies from patients with ulcerative colitis produce soluble mediators that activate neutrophils and promote neutrophil–endothelial adhesion.

Coloproctology 003

A prospective randomized trial of total intravenous anaesthesia with epidural or opiate analgesia in elective colorectal surgery

F.G. Bergin, P.A. Mallinder, P. Royle, K. Wilson and D.J. Leaper
North Tees General Hospital, Stockton-on-Tees, Cleveland

Background: The aim of this study was to compare differing anaesthetic and analgesic techniques on peri-operative outcomes of colorectal surgery.
Method: In this prospective randomized trial, 35 patients so far have been entered into four treatment arms. All received trial of total intravenous anaesthesia (TIVA) and either inhaled nitrous oxide/oxygen mixture or air/oxygen. Peroperatively patients received either intravenous morphine or epidural bupivacaine, analgesia, maintained postoperatively as patient-controlled analgesia (PCA) or by continuous epidural infusion.
Result: Peroperatively, patients who had epidurals tended to have less operative blood loss (median 780, range 200–2625 ml) than the morphine group (median 1425, range 250–2725 ml) and fewer of them were transfused postoperatively (24 per cent vs 61 per cent; $P<0{\cdot}05$). Pain relief, measured subjectively (defined as excellent/good or fair/poor) was significantly better in those who had an epidural (83 per cent vs 44 per cent; $P<0{\cdot}005$). Return of intestinal function was assessed by measuring days to return of bowel sounds, first flatus and first bowel action with trends suggesting an advantage to the epidural group. The time to full mobility postoperatively was also less in the epidural group and in particular the patients who had epidural/nitrous oxide (median 4·6 days vs 6·0 days).
Conclusion: The use of epidurals for colorectal surgery is associated with a reduction in blood loss, transfusion requirements, gives superior pain relief and may afford earlier return of intestinal function and mobility.

Coloproctology 004

The strength–duration curve combined with manometry of the external anal sphincter: a powerful assessment of neuromuscular integrity?

D.N. Monk, P. Mills, J. Jeacock, M. Deakin, A. Cowie and E.S. Kiff *University Hospital of South Manchester, Wythenshawe, Manchester*

Background: The strength–duration curve of a muscle is thought to be a measure of its innervation. This study evaluates manometry and the strength–duration curve of the external anal sphincter for discriminating between controls and patients with faecal incontinence.
Method: Forty-three female patients with disordered defaecation, predominantly incontinence were studied along with 45 age-matched females with no disorders of defaecation. A full lower gastro-intestinal history, strength–duration curve of the external anal sphincter, ano-rectal manometry and pudendal nerve terminal motor latency were recorded.
Results: Logistic regression was performed using resting and voluntary squeeze pressure and current strengths at 28 different pulse durations to develop a predictive equation for group membership. It was found that only the currents at 1 and 6 ms were significant predictors of group membership. When ano-rectal manometry data were included only the current required to elicit contraction at 1 ms was required. The following regression equation can be applied to predict continence in this population with a sensitivity of 95 per cent and specificity of 100 per cent. A negative value indicates continence.
$\mathrm{Logit}\ (P) = 4{\cdot}1605 - 0{\cdot}0559 \times \text{Squeeze pressure} - 0{\cdot}1755 \times \text{Resting pressure}\ 0{\cdot}86221_{\mathrm{Ams}}$
Conclusion: These data show that data from the strength–duration curve can be used in conjunction with ano-rectal manometry to produce a powerful discriminatory tool for faecal incontinence. This simple and inexpensive technique may have a role in evaluation of the neuromuscular integrity of the anal sphincter in the investigation of patients with faecal incontinence.

Coloproctology 005

Outcome following perianal fistula surgery: predictive value of magnetic resonance imaging

K.S. Chapple, J.A. Spencer*, D. Wilson*, J. Ward*, A.C.J. Windsor and N.S. Ambrose *Departments of Surgery and *Radiology, St. James's University Hospital, Leeds*

Background: The aim of this study was to assess the ability of preoperative magnetic resonance imaging (MRI) to predict clinical outcome following surgery of perianal fistulas.

Method: A cohort of 37 patients with active perianal fistulas was assessed by MRI with the dynamic contrast-enhanced technique. This was performed prior to surgical exploration and management as part of a prospective blinded study. Outcome for this cohort was assessed at a minimum of 1 year after surgical exploration. Outcome was then correlated in a blinded fashion with the surgical and magnetic resonance (MR) grading of the severity of the fistulous disease.

Results: MRI was better than surgical exploration at predicting outcome (MRI positive predictive value (PPV) 73 per cent, negative predictive value (NPV) 87 per cent, sensitivity 89 per cent, specificity 68 per cent; surgical exploration PPV 57 per cent, NPV 64 per cent, sensitivity 73 per cent, specificity 47 per cent). MR classification of fistulas was significantly associated with outcome ($P = 0{\cdot}0004$) and surgical classification was not significantly associated ($P = 0{\cdot}22$) with outcome (χ^2 test). There was a significant difference between the MR grades of patients with satisfactory and unsatisfactory outcomes ($P < 0{\cdot}001$, Mann–Whitney U-test).

Conclusion: As well as accurately determining the surgical anatomy of perianal fistulae MRI better predicts clinical outcome than surgical exploration. Dynamic contrast-enhanced MRI is of value in the management of perianal fistulas.

Coloproctology 006

Pre-operative radiotherapy for rectal cancer: who needs it?

A.F. Horgan and I.G. Finlay *Department of Coloproctology Glasgow Royal Infirmary University NHS Trust, Glasgow*

Background: Adjuvant preoperative radiotherapy has been advocated for all patients with rectal cancers in an attempt to reduce local recurrence. This approach leads to over-treatment and toxicity in the majority of patients who are not at risk of local recurrence.

Method: We reviewed 114 consecutive patients who presented with rectal cancer under the care of a single surgeon over a 5-year period. Follow-up was for a minimum of 2 years. Patients were placed in palliative or curative groups preoperatively on the basis of a pelvic computed tomography scan or examination under anaesthesia. Preoperative radiotherapy was offered to patients with locally advanced tumours.

Results: Of these 114 patients, 78 underwent anterior resection; 36 patients with tumours >10 cm from the anal verge underwent anterior resection with a handsewn anastomosis. Sixty-six patients with tumours <10 cm from the anal verge underwent total mesorectal excision (TME) with a double stapled coloanal anastomosis in 42 patients, and an abdomino-perineal resection in 24 patients. There was one perioperative death (0·8 per cent) and three anastomotic leaks. Seventy-three per cent of operations were considered curative on the basis of preoperative staging. Of these, three (3·9 per cent) went on to develop local recurrence and 10 patients (13·1 per cent) developed disseminated disease. In the palliative group, 14 (44 per cent) patients had preoperative evidence of locally advanced disease. Of these, 10 (71 per cent) died within 1 year due to advanced disease or local recurrence. All four patients who did not develop local recurrence had lateral resection margins which were free of tumour.

Conclusion: These data suggest that preoperative staging can predict with accuracy those patients at risk of developing local recurrence and preoperative adjuvant therapy can therefore be restricted to this group.

Coloproctology 007

Can simple delivery data predict the likelihood of an obstetric anal sphincter injury?

A. Varma, J. Gunn, S.W. Lindow and G.S. Duthie *Academic Surgical Unit, Castle Hill Hospital, Cottingham (part of the University of Hull Postgraduate Medical School)*

Background: Anal sphincter injury is recognized in relation to childbirth. Previous authors are inconclusive as to which delivery variables are associated with such damage and may be useful in predicting its occurrence.

Method: A prospective study was undertaken to determine whether baby weight, head circumference, length of second stage and active pushing could be correlated to occurrence of anal sphincter injury. One hundred and fifty-nine women delivering at a single unit were assessed using anal endosonography and delivery data were evaluated to see if a statistically significant difference existed in the presence of sphincter trauma.

Results: There were no third-degree tears in the group; endosonography revealed sphincter disruption in 8·7 per cent of those delivering normally and in 83 per cent of those requiring forceps. No correlation was detected between any of these variables and the presence of sphincter injury (Mann–Whitney U-test and Spearman correlation).

Conclusion: Besides forceps delivery, delivery variables previously perceived as potential predictors of sphincter injury are not useful in predicting its occurrence. With a low incidence of sphincter injury in normal deliveries routine postnatal assessment is not warranted but should be mandatory for all instrumental deliveries.

Coloproctology 008

The effect of direct electrical stimulation on the intact colon

A. Maw, M-A. Pilot, M.R. Hutton, A.J.P. Eccersley, A. Basu, M. Scott and N.S. Williams *Academic Department of Surgery, St Bartholomew's and the Royal London School of Medicine and Dentistry, Queen Mary and Westfield College, London*

Background: Colonic dysmotility caused by intrinsic abnormalities or following surgery may result in ineffective rectal evacuation. Electrical stimulation has been shown to produce contractions in isolated colonic smooth muscle and isolated colonic pouches but there are no studies investigating its potential to produce propulsive contractions in the intact colon.

Method: Experiments were performed on nine (20 kg) pigs under general anaesthesia. At laparotomy, a DS7 constant current stimulator delivered pulsed, monophasic, square wave impulses, of 2 min duration, to pairs of bi-polar stainless steel electrodes positioned within the muscularis propria at the caecal pole (CP) and opposite the ileocaecal valve (ICV). Serosal strain gauges recorded smooth muscle activity. Intraluminal responses to stimulation were measured using a compliant balloon connected to a barostat and by solid-state pressure transducers.

Results: The threshold current and pulse width relationship was exponential and maximum contractile response occurred with a stimulus of 10 Hz, 2 ms, 100 mA. Median unstimulated intraluminal pressure was 3·4 mmHg (range 1·1–5·6). Maximal stimulation between CP electrodes caused localized, non-propagated contractions [median pressure rise 4·1 mmHg (range 2·1–13·3)] whereas cross stimulation between CP and ICV electrodes caused mass caecal contraction [median pressure rise 10·5 mmHg (range 5·3–13·3) $^{*}P = 0{\cdot}006$]. A dose–response curve for contractile amplitude was seen with alterations in current and pulse width. Stimulation produced reductions in caecal volume of up to 100 per cent, changes being greater with cross caecal stimulation at any given inflation pressure of the barostat balloon (Table).

	Median percentage reduction in barostat balloon volume (range)		
Barostat pressure	ICV to CP electrode (range)	CP electrode pair (range)	Probability
5 mm Hg	72 (15–100)	22 (4–50)	$^{*}P = 0{\cdot}002$ ($n = 12$)
10 mm Hg	45 (19–64)	13 (4–45)	$^{*}P = 0{\cdot}002$ ($n = 12$)
15 mm Hg	21 (16–27)	7 (4–9)	$^{*}P = 0{\cdot}18$ ($n = 2$)

* = Wilcoxon matched pairs signed rank test

Conclusion: Electrical stimulation of the intact porcine caecum generates propulsive contractions capable of producing evacuation at physiological intraluminal colonic pressures. This has a number of potential applications in the treatment of disorders of colorectal evacuation and in total anorectal reconstruction.

Coloproctology 009

Long-term function of the electrically stimulated gracilis neosphincter

A.J.P. Eccersley, A. Maw and N.S. Williams *Academic Department of Surgery, Queen Mary and Westfield College, London*

Background: Most reports of the electrically stimulated gracilis neosphincter (ESGN) describe only short-term outcome, with little information available on longer-term continence. This study aimed to assess function and physiology in patients who had an ESGN constructed more than 5 years ago.
Method: Records of all 31 patients who underwent an ESGN from 1988–92 for intractable faceal incontinence or as part of total anorectal reconstruction were reviewed. The 14 patients who retained the ESGN for more than 5 years were identified and their long-term continence, anorectal physiology and electrical stimulation parameters were assessed.
Results: After a median follow-up of 80 (range 50–107) months from stoma closure, Cleveland clinic continence scores improved from 20 (16–20) preoperatively to 8 (2–14) at 5 years. The batteries of nine prototype stimulators became depleted, of which three were replaced once and three twice, giving a median battery life of 35 (9–80) months. Over 5 years median stimulation threshold increased from 0·75 V (0·3–3) to 1·2 V (0·4–7·0) but sphincter function remained satisfactory with median resting and squeeze pressures 21 (10–40) and 54 (35–90) cm H_2O. Survival curve analysis revealed that long-term continence was most likely in patients treated for traumatic anorectal injuries, and was more likely in those who had an Alpha (nine out of 16 after 5 years) rather than a Gamma (three out of 14) wrap.
Conclusion: Long-term continence and sphincter function can be obtained with the ESGN, despite episodes of battery depletion.

Vascular 001

The fate of patients undergoing surveillance of small abdominal aortic aneurysms

R.B. Galland, M.S. Whiteley and T.R. Magee *Royal Berkshire Hospital, Reading*

Background: Increasing numbers of patients with small abdominal aortic aneurysms (AAA) are being diagnosed. The aim of this paper is to define the fate of those patients undergoing surveillance of small AAAs.
Method: A prospective study has been carried out of all patients undergoing surveillance. At the time of the first consultation the patient was assessed, a Detsky score calculated and the referral source noted. End points of the study were elective repair of the aneurysm, aneurysm rupture or death of the patient.
Results: Details of 267 patients were analysed. The referral source was general practitioner in 39 per cent, patients with peripheral vascular disease in 32 per cent and department of urology in 21 per cent. No patients were referred from population screening. The cumulative 5-year risks of rupture, elective repair or non-AAA-related deaths were 15 per cent, 26 per cent and 46 per cent for all patients, 4 per cent, 13 per cent and 38 per cent for patients initially presenting with AAA of <4 cm diameter and 21 per cent, 42 per cent and 54 per cent for patients presenting with an AAA of 4–5·5 cm diameter. All but one of 11 patients whose aneurysm ruptured were unfit or had declined elective repair. There were 56 non-AAA-related deaths, the majority due to cardiovascular causes. Those patients with low Detsky scores had a 5-year survival of 62 per cent, those with high scores 44 per cent. The age/sex-matched survival of a normal population at 5 years is 80 per cent.
Conclusion: Overall the non-AAA-related mortality was greater than the risks of rupture or elective repair. It is important to bear in mind the poor prognosis of this group of patients compared with a normal population when considering elective repair of small AAAs.

Vascular 002

Growth rate of abdominal aortic aneurysms: how frequently should they be scanned?

P.S. Basnyat, S. Chawda, E. Morgan*, E. Townsend, R.K. Winter and M.H. Lewis *East Glamorgan General Hospital and *University of Glamorgan*

Background: There is no agreed consensus on how often a patient should be followed-up once an abdominal aortic aneurysm (AAA) is detected. The aim of this study was to assess growth rate of AAA on our follow-up programme and to determine the current protocol needed modification.
Method: We have been running an AAA screening programme for hypertensives since 1994. All patients followed-up for AAA by ultrasound between 1994–1996 were included. Those with only one scan were excluded from the study. Our current protocol is annual ultrasound scan for AAA less than 3·9 cm and scans at intervals of 6 months for aneurysms greater than 4 cm.

AAA size (cm)	Number of patients	Sex		Mean age (years)	Mean growth (cm/year)	Maximum growth (cm/year)
		Male	Female			
<2·9	32	25	7	73	0·07	0·38
3–3·4	63	49	14	71	0·15	0·6
3·5–3·9	38	30	8	73	0·17	0·8
4–4·4	22	20	2	72	0·21	1·1
4·5–4·9	11	8	3	79	0·23	0·45
>5	5	4	1	74	0·29	0·56

Conclusion: Maximum growth rate of AAA in each group should be considered when deciding on scanning intervals. We suggest an abdominal aorta of less than 2·9 cm should be scanned every 3 years, 3–3·4 cm at intervals of 2 years, 3·5–3·9 cm annually and those above 4 cm should be scanned every 6 months.

Vascular 003

Intravascular ultrasound in stenting for aortic occlusive disease

M. Thornton, M.R. Rees, A. Jones, P. Murphy, R.N. Baird, P.M. Lamont and F.C.T. Smith *The Vascular Unit, Bristol Royal Infirmary, Bristol*

Background: Intravascular ultrasound (IVUS) allows assessment of endoluminal and vascular wall morphology. The role of IVUS as a tool in assessment of aortic stent placement and follow-up, for occlusive disease, was investigated and compared to angiography.
Method: IVUS was carried out using a mechanical rotating head system with either a 30 MHz Dumed, or a 20 MHz CVIS system. The IVUS catheter was introduced percutaneously by retrograde femoral route prior to carrying out imaging. Aortic diameter at, above and below the site of the lesion was measured. Balloon size and endovascular stent were selected on the basis of IVUS measurements, and guided under fluoroscopic control to the lesion site. The stent was placed under fluoroscopic control. After placement, the stent was imaged by IVUS.
Results: IVUS was used to assess 13 stents (12 Palmaz and one Nitinol Memotherm) placed for severe symptomatic ischaemia of the lower limbs in nine patients (five male, four female; age range 57–80 years). Eight stents were imaged at time of placement and five at follow-up when patients developed recurrent symptoms of ischaemia. In all cases following balloon angioplasty under fluoroscopic control, IVUS revealed under-expansion of the stent (mean 3 ± 0·9 mm), compared to angiography, necessitating further angioplasty. Maximum balloon diameter was 14 mm and stent expansion ranged from 10–12·85 mm. Symptomatic recurrence was found to be due to thrombus formation, stent irregularity and under-expansion.
Conclusion: IVUS demonstrates that stent under-expansion is a common phenomenon in large-sized stents placed for aortic occlusive disease. This factor may be significant in recurrent problems following endovascular stenting.

Vascular 004

A comparison of mortality in screened and non-screened patients undergoing elective aortic aneurysm repair

C.D. Irvine, E. Shaw, K. Poskitt, M.R. Whyman, J.J. Earnshaw and B.P. Heather *Gloucestershire Vascular Group*

Background: The main benefit of abdominal aortic aneurysm (AAA) screening should be derived from the differences in the mortality between elective and ruptured AAA repair. The aim of this study was to compare the mortality rates for elective repair in screened and non-screened detected AAAs.
Method: Patients undergoing elective AAA repair were either from a current screening programme to detect men over 65 years with AAAs (screened), or were referred from other sources (non-screened). Aneurysms presenting acutely but having non-urgent surgery were included. Mortality data relating to these patients were studied.
Results: Three hundred and twenty-eight aneurysm repairs were performed with a median of 45 repairs per annum (range 32–62) and with an overall mortality of 6·4 per cent. The yearly data for number of operations and mortality are shown for the screened, non-screened and total county populations. The proportion of screened operations rose with time but there was no increase in the total number performed.

	1991	1992	1993	1994	1995	1996	1997	Total/% mortality
Number								
Screened operations	11	10	13	23	19	36	18	130
Non-screened operations	38	22	26	39	26	28	19	198
County	49	32	39	62	45	64	37	328
Mortality								
Screened operations	1	0	0	0	3	2	0	6* (4·6%)
Non-screened operations	5	2	2	2	2	2	0	15* (7·6%)
County	6	2	2	2	5	4	0	21* (6·4%)

*χ^2 test, P=N.S.

Conclusion: Screened patients had a similar mortality to non-screened patients for AAA repair. The screening programme has not increased the annual cost of elective repair of AAA as, despite increasing numbers of screened operations, the total number of AAA repairs performed per annum has not increased.

Vascular 005

Fast contrast-enhanced magnetic resonance angiography of the aorta and lower extremity vessels using a novel approach

J.F.M. Meaney, I. Robertson, S. Chakravarti, S. Selvakumar, J. Scott, P. Vowden, M.J. Gough and S. Homer-Vanniasinkam *ULTH NHS Trust, The General Infirmary at Leeds, Leeds, West Yorkshire*

Background: The aim of this study was to develop an approach for magnetic resonance imaging (MRI) of the aorta and lower extremity vessels using fast contrast-enhanced magnetic resonance angiography (MRA).
Method: We devised a novel approach for contrast-enhanced MRI of the aorta and lower extremity vasculature by moving the table on which the patient lies between three successive imaging acquisitions centered over the aorto-iliac, femoro-popliteal and below-knee segments, thus allowing imaging over a sufficiently large region of interest. Digital image subtraction was employed to improve image quality. Twenty patients with intermittent claudication underwent both conventional catheter angiography and gadolinium-enhanced MRA with this new technique at 1·5 Tesla of the aorta and outflow vessels.
Results: Compared to catheter arteriography MRA had 95 per cent sensitivity and 98 per cent specificity for demonstration of occlusions, but MRA confirmed patency of numerous segments thought to be occluded using the conventional method. There was good interobserver correlation between the two readers overall with a weighted kappa of 0·834 for all lesions, kappa 0·861 for reporting of insignificant (<50 per cent) stenoses compared to significant (>50 per cent) ones, and kappa 0·917 for reporting of occluded vs patent (0–99 per cent stenosis) segments.
Conclusion: This technique shows high accuracy compared to catheter arteriography in patients with occlusive arterial disease of the aorta and outflow vessels. Our preliminary results suggest that this technique may ultimately provide a safe, non-invasive and cost-effective alternative to catheter arteriography.

Vascular 006

Renal artery stenosis: the significance of its incidental finding on peripheral angiography

P.D.F. Dodd, J.B. Fitzgerald, M. Bukhari, L. Gurnani, M.S. Baguneid, G.D. Griffiths, N. Chalmers and M.G. Walker *Department of Vascular Surgery, Manchester Royal Infirmary, Manchester*

Background: As more angiograms are being performed for lower limb ischaemia renal artery stenosis (RAS) is increasingly diagnosed as an incidental finding. We aimed to determine the prevalence of RAS in patients with peripheral vascular disease and its impact on patient outcome.
Method: All peripheral angiograms performed over a 2-year period were independently reviewed to determine the degree of RAS. Those patients found to have RAS of 50 per cent or more were then studied further. Mortality risk factors were recorded and statistical analysis performed using χ^2 tables with Yates' correction. Follow-up was available for a minimum of 2 years and a maximum of 4 years.
Results: Analysis of 1102 consecutive angiograms revealed 156 (14·2 per cent) patients with RAS. In this group there was a high overall mortality rate of 21·2 per cent. Hypertension and diabetes were common, 62·7 per cent and 20·6 per cent respectively, while elevated serum creatinine >130 µmol/l was found in 10·9 per cent. Bilateral or severe unilateral stenosis >90 per cent was identified in 43·6 per cent. However the only risk factor useful in identifying a high mortality subgroup was elevated baseline creatinine (P=0·004, two-tailed t-test).
Conclusion: We conclude that the prevalence of RAS merits flush aortography to visualize the renal arteries in all patients undergoing peripheral angiography. Furthermore, any patient with pre-existing elevation of creatinine and RAS is at exceptionally high-risk and merits urgent investigation of renal and cardiac function.

Vascular 007

A prospective study of internal carotid artery plication during carotid endarterectomy: early clinical and duplex outcome

K.R. Makhdoomi, *K. McBride, A.W. Bradbury and C.V. Ruckley *Vascular Surgery Unit and *Department of Medical Imaging, University Department of Surgery, Royal Infirmary, Edinburgh*

Background: It has been suggested that the internal carotid artery (ICA) should be plicated during carotid endarterectomy (CEA) in order to exclude the distal intimal step and/or shorten the ICA, thus preventing turbulence and kinking. The aim of this study was to examine the early clinical and duplex outcome of patients undergoing CEA with plication.
Method: Analysis of a prospectively gathered computerized database comprising operative and clinical and duplex follow-up data pertaining to 212 consecutive CEAs performed between 1 November 1992 and 31 July 1997.
Results: Sixty patients (median age 68 years, range 49–85 years) undergoing 62 CEAs also had ICA plication because, in the opinion of the senior operator, the distal intimal step required 'tacking' down and/or there was a risk of postoperative kinking due to ICA redundancy. The plication technique will be described. Indications for CEA were transient ischaemic attack (TIA) 46 per cent, amaurosis fugax 19 per cent, TIA and stroke 13 per cent, TIA and amaurosis 11 per cent, and asymptomatic disease 11 per cent. All but one patient underwent patch angioplasty. There was one intraoperative stroke which was fatal (combined stroke and death rate 1·6 per cent) and two (3·2 per cent) transient ischaemic attacks. There was no other major morbidity and no patient suffered perioperative carotid thrombosis. Forty-six patients underwent postoperative duplex scan surveillance for a median of 12 (range 1–36) months: no abnormality was detected in 87 per cent; 9 per cent had restenosis <50 per cent and 4 per cent had restenosis 50–75 per cent. All restenoses were asymptomatic.
Conclusion: ICA plication is a useful, quick and technically straightforward means of excluding the distal intimal step and straightening the ICA. Plication avoids the need for arterial division or resection and does not adversely affect early clinical or duplex outcome after CEA.

Vascular 008

To compare clinical outcomes, length of stay and complications of local versus general anaesthetic for carotid endarterectomy

C. John, D. Williams and M. Horrocks *Department of Surgery, Royal United Hospital, Bath*

Background: The aim of this study was to review and compare the major and minor complication rates, length of stay, number of therapeutic interventions and outcomes of two cohorts of patients undergoing carotid endarterectomy for symptomatic carotid stenosis.

Method: One hundred patients, 50 under general anaesthetic (GA) and 50 under local anaesthetic (LA), prospectively entered on to a carotid endarterectomy database, were retrospectively reviewed with reference to complication rate, blood pressure control, use of shunt, length of stay, therapeutic interventions and clinical outcome. For GA patients, shunts were inserted when the transcranial Doppler-assessed blood flow fell by >50 per cent. For LA patients, shunts were inserted for clinical neurological deficit. All patients were subject to on-table duplex scanning and subsequent vascular studies follow-up.
Results: There were no significant differences in stroke/death rates. No patient undergoing LA required a GA. There were no differences in minor complications (haematoma, transient nerve damage, transcranial ischaemic attack). Blood pressure control was significantly more stable in LA patients. Therapeutic interventions were a mean of six episodes for GA patients and one episode for LA patients. Length of stay was 2–3 days for GA and 1–2 for LA. There were no delayed complications related to early discharge and no differences in clinical outcome or restenosis at 2 months. Longer follow-up is awaited.
Conclusion: Carotid endarterectomy under LA seems to be a safe and effective method of performing the operation; it is associated with fewer therapeutic interventions, a more stable and faster recovery and shorter length of stay than GA.

Vascular 009

Carotid endarterectomy without angiography does not compromise outcome

I.M. Loftus, M.J. McCarthy, H. Pau, P.R.F. Bell, N.J.M. London and A.R. Naylor *Department of Surgery, University of Leicester, Leicester*

Background: Carotid angiography is associated with a 2 per cent risk of stroke and since the advent of colour duplex ultrasound, its role in the assessment of patients with carotid disease has been the subject of debate. The aim of this study was to evaluate a 5-year experience of carotid endarterectomy without routine angiography.
Method: A prospective audit of the results of carotid endarterectomy without routine angiography from January 1992 to December 1996. Angiography was performed only if the ultrasonographer was concerned about the distal or proximal extent of disease or to assess subocclusion.
Results: During the study period, 470 carotid endarterectomies were performed. Only 35 patients underwent carotid angiography. The indications for angiography were subocclusion in 22 patients, to assess the extent of proximal/distal disease in 12 and abnormal anatomy in one. Throughout the study period the overall perioperative death and/or stroke rate was 4·2 per cent. In 1997, the perioperative stroke rate had fallen to 1·3 per cent. In no case was the operation abandoned due to unexpected findings.
Conclusion: Although concerns exist about the precise duplex criteria for diagnosing a severe stenosis, this study has shown that a policy of selective angiography does not compromise patient safety or operability and avoids the unnecessary mortality, morbidity and costs associated with routine angiography.

Vascular 010

Endovascular stenting and traumatic aneurysms of the internal carotid artery

C.I.M. Clark, M.A. Al-Kutoubi*, A.O. Mansfield, A. Huang D. Baker and J.H.N. Wolfe *Vascular Surgery Unit and *Department of Radiology, St Mary's Hospital, London*

Background: The aim of this study was to assess our experience in the management of pseudoaneurysms of the internal carotid artery using endovascular stenting.
Method: Retrospective analysis of recent experience at one teaching hospital.
Results: Three young patients aged 19, 28 and 39 years presented with false aneurysms of the carotid artery. All three lesions arose as a result of road traffic accidents. At initial presentation, two patients had an ipsilateral stroke and all three had variable palsies of cranial nerves IX, X, XII and/or Horner's syndrome. One patient had bilateral carotid artery aneurysms. Intervention was indicated in order to prevent the development of a further stroke. All three lesions were treated by endovascular stent placement introduced via a femoral arterial puncture. In one patient, tungsten coils were also placed within the aneurysm sac. All three false aneurysms were completely excluded and there were no procedure-related complications. During the follow-up period (2, 3 and 28 months) the lesions have remained excluded with continued carotid artery patency and no further neurological symptoms.
Conclusion: Our early experience encourages us to continue with this technique, supplemented with careful follow-up as little is known about the optimum choice of stent.

Vascular 011

Carotid endarterectomy: practice and outcome before and after ECST and NASCET

J. Brittenden, A.W. Bradbury, J.A. Murie, A.McL. Jenkins and C.V. Ruckley *Vascular Surgery Unit, University Department of Surgery, Royal Infirmary, Edinburgh*

Background: The European Carotid Surgery Trial (ECST) and the North American Symptomatic Carotid Endarterectomy Trial (NASCET), published in 1991, demonstrated the benefit of carotid endarterectomy (CEA) in patients with high-grade symptomatic internal carotid artery stenosis. This study examines changes in practice and outcome of CEA before and after publication of these trial data.
Method: Analysis of a computerized database gathered 557 primary CEAs performed between January 1975 and October 1997. Two time periods are compared.
Results: Although clinical indications for CEA have not significantly changed, operated patients now represent a higher risk group in terms of co-morbidity, presence of infarct on computed tomography and severity of arterial disease. There has been a significant increase in the use of shunting and patch angioplasty. The proportion of patients operated for asymptomatic disease remains small.

	1975–1991 $n=260$ (%)	1992–1997 $n=297$ (%)	P value (Fisher's exact test)
Amaurosis fugax/retinal artery occlusion	102/13	107/12	NS
Transient ischaemic attack	161	165	NS
Preoperative stroke (recovery/persistent deficit)	34/39	43/52	NS
Asymptomatic	12	22	NS
Established hypertension	98 (38)	153 (52)	<0·005
Diabetes	15 (6)	32 (11)	<0·05
Infarct on preoperative CT	55/170 (32)	72/144 (50)	<0·005
Operated stenosis > 75%	74 (28)	220 (74)	<0·0001
Shunt used	72 (28)	108 (36)	<0·03
Patch angioplasty	168 (65)	247 (83)	<0·0001
Total perioperative neurological event rate	30 (11·5)	17 (5·7)	<0·02

Conclusion: Since ECST and NASCET there has been a four-fold increase in the numbers of CEA performed annually. Despite operating on higher risk patients there has been a significant and continuing reduction in perioperative morbidity.

Serum VEGF in breast cancer: relationship with stage, type and receptor status

K. Heer, H. Kumar, P.J. Drew, J.N. Fox, P.J. Carleton, J.R.T. Monson and M.J. Kerin *The University of Hull, Academic Surgical Unit, Castle Hill Hospital, Cottingham, East Yorkshire*

Background: Vascular endothelial growth factor (VEGF), is one of the most potent angiogenic cytokines. Tumour levels correlate with micro vessel density, nodal metastasis and disease-free survival. This study evaluates the relation between serum VEGF and various pathological indices of breast cancer.
Method: Serum VEGF165 was assayed preoperatively in 135 patients with breast cancer and compared to serum VEGF levels in 72 healthy women. All tumours were staged by a single pathologist according to the TNM classification.
Results: Serum VEGF was elevated in all stages of breast cancer. Levels in nodal, recurrent and metastatic disease were significantly higher than controls. Patients with ductal carcinoma *in situ* (DCIS) had elevated levels compared to controls. Elevated VEGF levels were observed in 67·5 per cent of patients compared to 11·2 per cent patients with raised CA15-3 and 13 per cent with abnormal CEA levels.

	Median (IQR) VEGF pg/ml	P (value vs controls)
Controls ($n=72$)	173·8 (92·5–252·5)	
DCIS ($n=8$)	450·4 (301·8–795·2)	$P=0{\cdot}002$
Ductal carcinoma ($n=95$)	307·7 (155·5–483·0)	$P<0{\cdot}0005$
Lobular carcinoma ($n=16$)	207·1 (118·7–379·8)	$P=0{\cdot}32$
ER positive ($n=62$)	305·9 (179·7–485·2)	$P=0{\cdot}0005$
ER negative ($n=20$)	267·8 (94·2–523·7)	$P=0{\cdot}1$

VEGF levels were not significantly elevated in patients with lobular cancer or those with ER-negative tumours.

Conclusion: Serum VEGF shows a correlation with not only tumour stage and cancer cell type, but also with oestrogen receptor (ER) status. This may have implications in the study of hormones in the aetiology, pathogenesis and prognosis of breast cancer. Serum VEGF is more sensitive than currently employed tumour markers and it may have a role in monitoring disease prognosis in breast cancer patients.

Breast 002

Comedo ductal carcinoma *in situ*: anti-oestrogen therapy does not increase apoptosis nor decrease proliferation

A. Gandhi, P.A. Holland, W.F. Knox, A.D. Baildam, C.S. Potten and N.J. Bundred *Department of Surgery, Pathology and Epithelial Biology, University of Manchester, Manchester*

Background: Over 50 per cent of screen-detected ductal carcinoma *in situ* (DCIS) lesions are of the comedo subtype which are usually oestrogen receptor-negative. The value of postoperative anti-oestrogen (AE) therapy in preventing recurrence following breast conserving surgery for DCIS is currently under evaluation in two national trials. Using an *in vivo* model for human DCIS, the effect of E_2 and AE treatment on programmed cell death (apoptosis) and cellular proliferation (Ki67 immunoreactivity) in DCIS lesions was examined.
Method: In each of 20 experiments, a median of 16 athymic nude mice (range 12–20) were implanted with eight DCIS xenografts per mouse and given either no treatment, a subcutaneous slow release 2 mg β-oestradiol pellet (E_2) or a weekly injection of 0·1 ml Faslodex^{TM} (a pure AE) for 2 weeks. Xenografts were then removed and apoptotic and Ki67 indices compared between treatment groups by examining cell morphology on H&E sections (no. cells exhibiting apoptosis/total no. cells counted) or by immunohistochemistry (Ki67 proliferation index).
Results: All non-comedo lesions and three of 15 comedo DCIS lesions were oestrogen receptor-positive. Pretreatment apoptotic and proliferative rates were significantly higher in comedo than non-comedo lesions ($P<0{\cdot}001$ and $P=0{\cdot}02$ respectively). E_2 or AE therapy had no significant effect upon comedo DCIS whereas in non-comedo DCIS E_2 treatment resulted in increased proliferation ($P=0{\cdot}03$) and apoptosis ($P=0{\cdot}006$) whilst AE treatment resulted in increased apoptosis alone ($P=0{\cdot}04$) compared to controls.

	Comedo DCIS ($n=15$)		Non-comedo DCIS ($n=5$)	
Median (range)	Apoptotic index	Ki67 index	Apoptotic index	Ki67 index
Pretreatment	1·6% (0·7–3·7)	16·2% (7–46)	0·4% (0·1–0·6)	2·2% (0–16)
Control group	1·4% (0–3·5)	16·9% (2–29)	0·4% (0·1–1·7)	7·0% (2–21)
E_2 group	1·3% (1·7–2·6)	17·5% (7–46)	1·5% (0·3–2·3)	10·5% (6–31)
Anti-oestrogen group	0·8% (0·4–3·6)	14·8% (14–18)	1·0% (0·5–2·0)	8·1% (4–11)

Conclusion: Non-comedo DCIS (usually ER positive) is responsive to hormonal manipulation but women with comedo DCIS (usually oestrogen receptor-negative) are unlikely to benefit from AE therapy and other therapeutic strategies need to be investigated.

Breast 003

The specialist treatment of the axilla

D.B. Kingsmore, A. Ssemwogerere*, D. Hole*, C.R. Gillis* and W.D. George *Department of Surgery, Western Infirmary, and *West of Scotland Cancer Surveillance Unit, Ruchill Hospital, Glasgow*

Background: Previous reports have highlighted both the survival advantage of treatment by larger specialist breast units and also the poorer survival associated with inadequate axillary treatment for breast cancer. This report compares the adequacy of treatment of the axilla by specialists and non-specialist units and the outcome of this treatment.
Method: All 7144 histologically confirmed invasive breast cancers in women under 75 diagnosed from 1980 to 1994 who lived in a defined geographical area (population 1·5 million) were identified and the original pathology reports and 1950 out of 2531 case records for the years 1986–1991 obtained. The cause of death was derived from death certificate data.
Results: Specialists compared to non-specialists performed no axillary surgery in 448 (19 per cent) vs 1705 (36 per cent); inadequate sampling in 136 (6 per cent) vs 1013 (14 per cent); sampled 4–9 nodes in 927 (39 per cent) vs 2301 (32 per cent); and 10+ nodes in 828 (35 per cent) vs 1313 (18 per cent): χ^2 = 10007·70, 4DF, $P<0{\cdot}00000$. From the case records: specialists compared to non-specialists performed no axillary treatment in eight (1 per cent) vs 148 (15 per cent); sampled less than four nodes only in 40 (5 per cent) vs 115 (11 per cent); sampled less than four nodes in 12 premenopausal women vs 124 (5 per cent vs 40 per cent of all premenopausal women treated); did not remove any axillary nodes in an axillary sample in six (15 per cent of women with an axillary sample performed) vs 51 (44 per cent). Axillary recurrence was noted in 24 (3 per cent) vs 84 (8 per cent). When examined at 3-year intervals, the specialists have removed four or more nodes in 90 per cent of women with axillary surgery performed, whereas the non-specialists have improved from 66 per cent in the first to 81 per cent in the last interval.
Conclusion: Specialists examine the axilla more frequently, more thoroughly, omit axillary surgery only in very selected cases, and consequently had a recurrence rate almost one third that of non-specialists.

Breast 004

Plasma thrombospondin in early and advanced breast cancer

G.J. Byrne, K.E. Hayden, L. Tetlow, R. Aggarwal and N.J. Bundred *University Hospital of South Manchester, Manchester*

Background: Thrombospondin (TSP) has been shown to promote metastasis in animal models by increasing adhesion of cancer cells to endothelial cells. We hypothesized that increased production of TSP by breast cancer would be associated with metastasis.
Method: TSP was measured in the plasma of women with early breast cancer (EBC) ($n=26$), advanced breast cancer (ABC) ($n=29$), women who had undergone surgery for breast cancer with no evidence of recurrent disease ($n=30$) and normal controls ($n=35$). Plasma TSP (pTSP) levels were measured in ng/ml by a radio-immunoassay developed at the University Hospital of South Manchester.
Results: pTSP in women with EBC (median 461 ng/ml, range 172–7750) was elevated when compared to women following surgery (median 230 ng/ml, range 154–547) ($P<0{\cdot}01$) and normal controls (median 180 ng/ml, range 142–356) ($P<0{\cdot}001$). Women with EBC who had nodal metastases ($n=12$) had higher levels of TSP than women who were node negative ($n=14$) ($P<0{\cdot}05$). pTSP in women with high-grade tumours (grades 2 and 3) ($n=16$) was raised when compared to grade 1 tumours ($P<0{\cdot}05$). pTSP levels in women with ABC (median 624 ng/ml, range 209–8820) were higher than in women with no evidence of recurrent disease ($P<0{\cdot}01$) and normal controls ($P<0{\cdot}001$).
Conclusion: Plasma thrombospondin levels are a marker of metastatic disease in early and advanced breast cancer and may be useful in assessing response to chemotherapy.

Breast 005

Tumour bed assessment in ductal carcinoma *in situ*

L.Y. Hiew, A.D. Purushotham, S. Stallard, C. Cordiner*, H. Dobson*, E.A. Mallon† and W.D. George *University Departments of Surgery and †Pathology, Western Infirmary and *West of Scotland Breast Screening Unit, Glasgow*

Background: Optimal surgical treatment for ductal carcinoma *in situ* (DCIS) involves a wide local excision to ensure tumour clearance. Several methods to assess margins have been described. The aim of this study was to investigate a method of tumour bed assessment by obtaining a shaving of the residual cavity following wide local excision.
Method: Fifty-four patients underwent wide local excision following initial diagnosis of DCIS by stereotactic biopsy or wire localization biopsy. Cavity shavings were obtained after wide local excision and sent separately for histopathology. This tissue was extensively blocked, serially sectioned and extent of residual disease noted. Further surgery was performed based on the extent of disease in the cavity shavings. Adjuvant treatment was administered to 32 patients (59 per cent). Nine patients received adjuvant radiotherapy alone, eight tamoxifen and radiotherapy and 15 tamoxifen alone. Mean follow-up was 35 months (range 4–92 months).
Results: Ten patients (18 per cent) had evidence of residual disease within the cavity shaving. Eight subsequently underwent re-excision or mastectomy. In two patients, no further surgery was performed as only a single focus of DCIS was noted within the tumour bed. The overall local recurrence rate was 7 per cent. All recurrences occurred in the tumour-bed negative group. The original pathology in these patients showed DCIS with high nuclear grade (2 or 3) and associated necrosis histologically and 3 of 4 were clinically palpable.
Conclusion: Obtaining a shaving of the tumour bed is a simple method of assessing residual disease and selective re-excision in tumour-bed positive patients appears to prevent local recurrence. Despite a negative tumour-bed, adverse clinico-pathological features may contribute to local recurrence. These patients may be more appropriately treated by mastectomy.

Breast 006

Axillary dissection is unnecessary in T1 breast cancers with negative sentinel nodes

A.D.K. Hill, D.C. Linehan, K.N. Tran, P.I. Borgen and H.S. Cody III *Memorial Sloan-Kettering Cancer Center, New York, USA*

Background: The aim of this study was to assess the relative value of lymphoscintigraphy (LSG), blue dye and radioisotope for breast cancer patients having sentinel lymph node biopsy (SLNB) by surgeons inexperienced with the technique and to evaluate the safety of avoiding an axillary dissection when the sentinel lymph node is disease free.
Method: In a prospective study, 110 patients with clinical T1-2N0 breast cancer had SLNB using a combination of lymphoscintigraphy, isosulfan blue dye and technetium sulphur colloid. All of the first 60 patients had a planned axillary dissection while the remainder only had an axillary dissection if the tumour was T2 in size or if the sentinel node was positive.
Results: The sentinel node was successfully identified by LSG in 58 per cent (61/106), by blue dye in 70 per cent (77/110), by isotope in 80 per cent (88/110) and by the combination of blue dye and isotope in 91 per cent (100/110) of all 110 patients ($P<0{\cdot}05$ for combination vs either alone; Fisher's exact test). Success in finding the sentinel node was unrelated to tumour size, type, histological grade or previous surgical biopsy. Failed procedures were no more than frequent in the early (5/55) than in the later experience (5/55). Among the first 60 patients who also had planned axillary dissection, the sentinel node was falsely negative in 2·0 per cent (1/48) of patients with T1 tumours and 17 per cent (2/12) of patients with T2 tumours. The negative predictive value of SLNB for T1 and T2 tumours was 97 per cent and 60 per cent, respectively.
Conclusion: In the first 110 sentinel lymph nodes biopsies, a combination of blue dye and isotope identified the sentinel node more successfully than either method alone. Axillary dissection is unnecessary in T1 breast cancer with a negative sentinel node.

Breast 007

The feasibility, safety, acceptability and cost analysis of early discharge following surgery for breast cancer

B.J. Mander, T. Qureshi, L. Strong† and G.C. Wishart *Departments of Surgery, and †Intensive Home Nursing Service (IHNS), Princess Royal Hospital, Haywards Heath, West Sussex*

Background: The major determinant of length of postoperative stay following surgery for breast cancer is the magnitude and duration of wound drainage. We wished to determine the feasibility, safety, acceptability and cost effectiveness of early discharge with drains *in situ* using a domicillary nursing service.
Method: The operative details, postoperative drainage, morbidity and analgesic requirements of 37 patients undergoing breast and axillary surgery were prospectively studied. Seventeen were discharged with suction drains *in situ* using the IHNS service. Twenty remained in hospital until drainage was <40 ml/24 h. Selection for early discharge was made using patient preference and geographical considerations. A postal survey was undertaken to assess patient satisfaction in the IHNS group.
Result:

	In patient ($n=20$)	Early discharge ($n=17$)
Age (years)	56·5 (36–75)	59·5 (36–75)
Length of postoperative stay (days)	7 (4–9)	3 (2–8)*
Total drainage (ml)	515 (142–1168)	480 (116–1069)
No. days drains left *in situ*	6 (2–8)	7 (4–11)**
Cost of postoperative care (£)	1500 (750–2000)	775 (300–900)***

Values are medians (ranges); *$P<0{\cdot}0001$, **$P<0{\cdot}05$, ***$P<0{\cdot}0002$, Student's t-test.

The complication rates in the two groups were similar and early discharge was not achieved at the expense of adequate postoperative analgesia.

Eighty-two per cent of the early discharge patients judged the service as excellent, 86 per cent felt they were discharged at the appropriate time and all patients questioned would readily use the service again if it were needed.
Conclusion: Early discharge is feasible, safe, popular and realizes considerable savings. With appropriate domicillary support it could be used in the majority of patients undergoing surgery for breast cancer.

Breast 008

Factors predicting completeness of excision of palpable breast cancers

J.M. Dixon, S. Greenwood* and P. Dillon *Edinburgh Breast Unit, Western General Hospital and *University of Edinburgh Medical School, Edinburgh*

Background: This study set out to identify factors available prior to surgery which are associated with completeness of excision of palpable breast cancers treated by breast conserving surgery.
Method: One hundred and sixty-two patients with palpable breast cancers who had attempted breast conserving surgery (wide local excision) where initial mammograms and complete clinical and pathological data were available were reviewed. Analysis was by χ^2 and Fisher's exact tests.
Results: There were 128 (79 per cent) complete excisions and 34 (21 per cent) had involved margins. Factors associated with an incomplete excision were a spiculated mass lesion or area of distortion vs other mammographic features, $P = 0{\cdot}0004$. Twenty-four of 34 incomplete excisions (70 per cent) had this feature. Lesions with spicules extending >50 per cent from the main mass lesion were particularly likely to be incompletely excised, $P = 0{\cdot}0002$. Microcalcification within or outwith a mass lesion and lesions visible on mammography also predicted incomplete excision, $P = 0{\cdot}028$, $P = 0{\cdot}014$, $P = 0{\cdot}023$, respectively. No other features including the experience of the operating surgeon were associated with completeness of excision.
Conclusion: It is possible to predict on the basis of mammographic appearance the majority of cancers that are likely to be incompletely excised by a wide local excision. Patients with these factors should have a very wide excision or should be warned about the possibility of an incomplete excision.

Breast 009

Captopril suppresses tumour-dependent angiogenesis but not physiological angiogenesis on the chick chorioallantoic membrane

R.A. Cochrane, E.L. Davies, M.K. Roy, H. Singhal, R.E. Mansel and P.D. Carey *The University Department of Surgery, University of Wales College of Medicine, Cardiff*

Background: Captopril is a widely used antihypertensive agent that works by inhibiting angiotensin converting enzyme (a zinc dependent carboxypeptidase), it also inhibits matrix metalloproteinases (MMPs) by a similar mechanism and has beneficial effects on several angiogenesis-dependent diseases such as cancer, diabetic retinopathy, arthritis and atherosclerosis. We have used a co-culture of the breast cell line MDA 231 and 'benign' fibroblasts KB 16Fs known to secrete active MMP 2 and 9 to induce angiogenesis on the chick chorioallantoic membrane (CAM) assay.
Method: Using stereoscopic microscopy blood vessels invading a 20 µl collagen gel on the CAM were counted through a 2 × 2 mm nylon mesh over 5 days. Captopril was added to the gels which were capped by a further 10 µl gel containing either no cells, 2×10^{-6} MDA 231s only or co-cultures with 2×10^{-5} KB16Fs. Results are expressed as a percentage of mesh squares containing blood vessels and median angiogenesis scores were compared against captopril-free controls using the Mann–Whitney U-test.
Results: Dose–response curves for captopril on the CAM at concentrations from 10^{-3} to 10^{-6} molar (M) revealed that 10^{-3} M was inhibitory ($P = 0{\cdot}0129$) but that 10^{-5} M ($P = 0{\cdot}0093$) and 10^{-6} M ($P = 0{\cdot}0084$) were stimulatory. MDA 231s and fibroblast co-cultures with 10^{-5} M ($P = 0{\cdot}033$) and 10^{-6} M ($P = 0{\cdot}0433$) captopril were significantly less angiogenic than controls.
Conclusion: When active MMPs are present, captopril reduces angiogenesis significantly at clinically achievable doses but lower doses appeared to enhance angiogenesis when no tumour cells were present. This observation that tumour-dependent angiogenesis is down-regulated and normal embryological angiogenesis is upregulated may suggest a different role for MMPs in both processes.

Vascular 012

Minimally invasive femoropopliteal revascularization: early results of our modified Moll remote superficial femoral endarterectomy

M.S. Whiteley, E.P.H. Torrie, T.R. Magee and R.B. Galland *Royal Berkshire Hospital, London Road, Reading*

Background: Minimally invasive vascular surgery should result in a shortened hospital stay, while achieving similar results to conventional surgery. We prospectively assessed a series of patients undergoing our modification of the Moll remote superficial femoral artery (SFA) endarterectomy procedure to assess the viability of this technique.
Method: The indication for Moll remote SFA endarterectomy is disabling claudication in patients who are suitable for above knee femoro-popliteal revasularization. The technique is performed through a single groin incision and does not require any graft material. After initial difficulties with our first two patients, we modified Moll's procedure by inserting a guidewire into the popliteal artery using a 'smart needle' preoperatively. This localizes the distal lumen after endarterectomy preventing atheromatous dissection while inserting the distal stent.
Results: Since February 1997, 21 patients have undergone the modified procedure.

	Technical failures	Successful procedures remaining 1^0 patent	Successful procedures but early occlusion (1 week)
Whole series ($n = 21$)	5	14	2
Learning curve ($n = 10$)	4	4	2
Subsequent cases ($n = 11$)	1	10	0

The mean length of operation was 91 min (range 50–135) and total length of hospital stay was a mean of 1·4 days (range 1–2 days).
Conclusion: Our modification of the Moll remote SFA endarterectomy compares favourably with other minimal access methods of femoropopliteal revascularization in terms of technical success and patency, and is attractive in terms of short operating time and hospital stay. We believe that this technique may become the procedure of choice for above knee femoropopliteal revascularization.

Vascular 013

Transduction of haemodynamic forces in vein graft endothelium by ion channels

J. Golledge, M. Gosling and J.T. Powell *Department of Vascular Surgery, Imperial College School of Medicine, Charing Cross Hospital, London*

Background: Arterial flow alters the adhesive and thrombotic surface of saphenous vein endothelium by inducing rapid upregulation of ICAM-1 and nitric oxide synthase (eNOS) and downregulation in thrombomodulin (TM) expression. The aim of this study was to investigate whether these effects are dependent on the following ion channels: stretch activated cation (SAC), calcium and ATP-sensitive potassium (K^+_{Ca2+} and K^+_{ATP}), and L-type calcium (Ca^{2+}) channels.
Method: Saphenous vein segments were perfused with oxygenated Krebs solution, mean pressure 100 mmHg, 80 cpm, shear stress 0·3 ± 0·1 N/m^2, in an *in vitro* bypass circuit for 90 min. Vein and endothelial viability were confirmed by ATP assay and CD31 staining. ICAM-1, eNOS and TM were assessed by immunostaining. Protein concentration was estimated by quantitative image analysis expressing staining as a percentage of control protein CD31. Gadolinium (Gd^{3+}, 10 μM), tetraethyl ammonium (TEA), 3 mM, glibenclamide (glib), 5 μM, and nifedipine (nif), 20 μM, were added to the perfusate in separate experiments to block SAC, K^+_{Ca2+}, K^+_{ATP}, and Ca^{2+} channels, respectively. Controls were freshly excised vein (basal) and vein exposed to venous flow (20 mmHg, 0·02 ± 0·01 N/m^2).
Results: These are given as percentage of CD31 area, mean ± standard error of six experiments. $^*P \leq 0{\cdot}01$ compared to arterial flow 90 min. No changes were observed after venous flow for 90 min.

Flow conditions	Channel blocked	ICAM-1	TM	eNOS
Basal	—	21·4 ± 1·4	68·4 ± 6·0	50·0 ± 5·6
Arterial flow (90 min)	None	44·6 ± 2·0	32·9 ± 3·0	70·1 ± 5·0
Arterial & Gd^{3+} (90 min)	SAC	21·2 ± 2·4*	75·6 ± 3·5*	84·5 ± 6·0
Arterial & nifedipine (90 min)	CA^{2+}	38·0 ± 2·3	78·0 ± 4·0*	55·8 ± 3·1*
Arterial & glibenclamide (90 min)	K^+_{ATP}	21·7 ± 3·5*	50·2 ± 6·0	66·1 ± 6·0
Arterial & TEA (90 min)	K^+_{Ca2+}	20·0 ± 1·0*	43·4 ± 4·0	47·0 ± 3·0*

Conclusion: Ion channels regulating the flux of K^+ and Ca^{2+} mediate mechanotransduction in saphenous vein endothelium, e.g. blocking Ca^{2+} entry prevents upregulation of eNOS whilst Gd^{3+} prevents the unwanted changes in ICAM-1 and TM. Selective ion channel blockade of ICAM-1 upregulation and TM downregulation may lead to a more favourable outcome to vein bypass.

Vascular 014

Lipid abnormalities in new referrals to vascular outpatients

R.P. Singam, A. Nasim, C. Sutton, M.J. Dennis, P.R.F. Bell and R.D. Sayers *Department of Vascular Surgery, Leicester General Hospital NHS Trust, Leicester*

Background: The aim of this study was to evaluate the benefits of a policy of performing screening blood tests in new patients with arterial disease referred to the vascular outpatients department.
Method: Clinical audit over a 12-month period of all new referrals with arterial disease to the vascular outpatients department at the Leicester General Hospital.
Results: Two hundred and seventy-two patients had at least one blood test performed at their outpatient visit. All of these patients had a full blood count performed, of which 21 results were abnormal. Further investigations of patients with abnormal results revealed one case of bladder cancer, one case of leukaemia and one patient with polycythaemia. Urea and electrolytes were measured in 269 patients (99 per cent). Of these 26 (10 per cent) were expectedly abnormal in patients with known renal impairment. A further 27 patients (10 per cent) were identified as having some degree of unrecognized renal impairment. Serum non-fasting glucose was measured in 252 patients (93 per cent). There were 11 unexpectedly raised results but further investigation of these patients diagnosed only one as diabetic. Serum cholesterol was measured in 201 patients (74 per cent). One hundred and thirty-two patients (66 per cent) had an abnormally raised serum cholesterol level. Of these only 12 patients (6 per cent) were known to have hyperlipidaemia.
Conclusion: Screening new patients with arterial disease in vascular outpatients identifies significant abnormalities, in particular renal impairment and hyperlipidaemia. Correction of these abnormalities may reduce the morbidity associated with contrast-induced nephrotoxic acute renal failure, and also contribute to secondary prevention of vascular events associated with raised lipids.

Vascular 015

Trends in lower limb amputee management: 3-year results from a national survey

M.E. Condie, S.P. Treweek and C.V. Ruckley* *National Centre for Training and Education in Prosthetics and Orthotics, University of Strathclyde, Glasgow and *Department of Vascular Surgery, University of Edinburgh, Royal Infirmary of Edinburgh, Edinburgh*

Background: This study had two aims: 1) to establish a system of data collection, audit and analysis for all lower limb amputees in Scotland, and 2) to create a demographic profile of the amputee population from which regional comparisons can be made.
Method: The Scottish Physiotherapy Amputee Research Group (SPARG), in collaboration with the Scottish Vascular Audit Group (SVAG) has developed a discharge summary form for all lower limb amputees. This was tested and introduced nationally in 1992. There are 24 designated SPARG hospitals spread throughout Scotland. Discharge forms are initiated at the amputating hospital and follow the patient should they be transferred. Ten hospitals enter data directly on to computer by means of SPARG software; others return forms to the SPARG co-ordinator. Patient numbers are checked with the Information and Statistics Division at the Scottish Office. Statistical analysis is carried out on three rehabilitation milestones: 1) number of days from amputation to casting (for prosthesis), 2) number of days from casting to delivery (of prosthesis, and 3) number of days from amputation to discharge. Analysis of compression therapy (CT) and early walking aid (EWA) use is also conducted.
Results: The amputee population is very stable. There are approximately 700 primary major amputations each year. Some 90 per cent of patients have peripheral vascular disease with 35 per cent reported as diabetic at the time of surgery. More than 60 per cent of amputations are at the transtibial (TT) and 30 per cent at the transfemoral (TF) level. Some 75 per cent of TT and less than 40 per cent TF amputees receive a prosthesis. Inpatient mortality is 14 per cent nationally (range 4–38 per cent). Stump infection occurs in 18 per cent of patients. Milestone data are broadly similar year to year although considerable differences are noted between centres. For TT amputees, crepe bandage as a CT confers no significant improvement over no compression bandage for 'days to casting' milestone, whereas use of an Elset 's' shrinker sock, or both, results in a reduced time ($P<0{\cdot}01$). Use of EWAs produces the same effect. Patients with a plaster cast as a compression dressing have a reduction in 'days to casting' compared to those using other CT ($P<0{\cdot}01$). 'Casting to delivery' times vary greatly. The figures for 'amputation to discharge' show a similar variation with a national mean of about 60 days for TT and 70 days for TF amputees (figures for patients fitted with a prosthesis). The one centre where a rigid postoperative dressing is routinely applied to TT amputees has a consistent and significant reduction in 'days to casting' ($P<0{\cdot}01$) and 'days to discharge' ($P<0{\cdot}05$) compared with the national average.
Conclusion: A national demographic profile has been established from which local comparisons, national and regional audit can be carried out. The apparent advantages to patients offered by the application of a postoperative rigid plaster-of-Paris dressing warrant further investigation.

Vascular 016

Ilio-popliteal grafts: a useful option for limb salvage

I.V. Mohan, D.J. Adam, R.T.A. Chalmers and C.V. Ruckley
Vascular Surgical Unit, University Department of Surgery, Edinburgh Royal Infirmary, Lauriston Place, Edinburgh

Background: The aim of this study was to assess the durability of bypass grafts using the iliac artery as the inflow vessel for patients with multilevel atherosclerotic occlusive disease.
Methods: Forty-six patients underwent bypass grafts from the iliac artery to the popliteal or tibial arteries. Surgery was performed for critical ischaemia in 43 cases and for severe claudication in three. Six patients had previous iliac angioplasty and eight had previous vascular surgical reconstructions. Two patients had had a contralateral major limb amputation. All patients had multilevel occlusive disease on arteriography. The profunda femoris artery was severely diseased in 18 patients (39 per cent). In a further 17 (37 per cent) the common femoral artery was also unreconstructable. Fifteen patients had three vessel run-off, 22 had two vessel run-off and nine patients had single vessel run-off. A retroperitoneal approach to the iliac artery was used in 31 cases, and extended longitudinal groin incisions in the others. All grafts were tunnelled extra-anatomically. The external iliac artery was used as the donor vessel in 36 patients and the common iliac artery in ten. Thirty-one grafts were inserted to the above knee popliteal artery, 13 to the below knee popliteal, and two to the posterior tibial artery. Externally reinforced polytetrafluoroethylene grafts were used in 40 cases and reversed long saphenous vein in six.
Results: Over a median follow-up of 22 (range 1–63) months, the observed median duration of graft patency was 19 (range 1–53) months for the above knee grafts, and 17 (range 1·5–63) months for below knee grafts. By life-table analysis, cumulative patency rates at 12 and 24 months were 73 per cent and 73 per cent, respectively for the above knee grafts, and 80 per cent and 67 per cent, respectively for the below knee grafts. Graft occlusion occurred in 12 patients (26 per cent), eight of whom required a major limb amputation (seven above-knee, one below-knee). One patient developed a graft infection; the graft was removed and he subsequently had an above knee amputation.
Conclusion: In patients with critical limb ischaemia due to complex multi-level atherosclerotic disease, the ilio-popliteal graft is a useful surgical option for limb salvage.

Vascular 017

Is formal quality-of-life analysis necessary in patients with lower limb ischaemia?

I.C. Chetter, J.I. Spark, D.J.A. Scott, P.J. Kent, D.C. Berridge and R.C. Kester *Department of Vascular Surgery, St James's University Hospitals, Leeds*

Background: Quality of life (QoL) is an increasingly popular outcome measure in vascular surgery. This prospective study aims to assess the correlation between the clinical indicators of lower limb ischaemia (LLI) and QoL.
Method: Over 2 years, 281 patients, 178 men and 103 women, median age 67 (range 40–87 years), underwent 1264 assessments. Patient-reported walking distance (PRWD), intermittent claudication distance (ICD), maximum walking distance (MWD) on a treadmill testing, ankle:brachial pressure indices at rest (ABPIR) and post-treadmill testing (ABPI PT) were recorded at each assessment if possible. Patients completed the EuroQol which derives three global QoL scores using categorical (Cat) data, time trade-off (TTO) data and a visual analogue scale (VAS).
Results:

		Spearman rank correlation coefficient		
Clinical indicators of lower limb ischaemia	*n*	EuroQol Cat	EuroQol VAS	EuroQol TTO
PRWD	1264	–0·44	0·53	0·62
ABPI R	1246	–0·27	0·24	0·35
ABPI PE	1067	–0·30	0·2	0·33
ICD	872	–0·25	0·29	0·34
MWD	1157	–0·36	0·47	0·57

Conclusion: Overall the correlation between QoL and clinical indicators of LLI is disappointingly low as reflected by the low correlation coefficients. This suggests QoL variations cannot be assumed to mirror variations in the clinical indicators of LLI, and independent QoL assessment is required.

Vascular 018

Peripheral thrombolysis and the fate of the claudicant

B.D. Braithwaite and The British Thrombolysis Study Group,
Queen's Medical Centre, Nottingham

Background: The aim of this study was to determine the outcome of patients who presented with sudden onset of incapacitating claudication and were treated with peripheral arterial thrombolysis within 2 weeks of the onset of symptoms.
Method: Some 108 patients (67 men, median age 69; range 29–94 years) were treated with intra-arterial tissue plasminogen activator thrombolysis at 14 hospitals between June 1992 and June 1997. The median duration of symptoms was 72 h (range 2 h to 2 weeks) and there were 52 graft occlusions (28 polytetrafluoroethylene, 14 vein, three Dacron, three composite, three unknown).
Results: Complete thrombolysis was achieved in 54 patients, clinically useful lysis in 25, lysis but no run-off in 19 and lysis failed in 10. Angioplasty of an underlying lesion was carried out in 39 patients; 10 had a thrombo-embolectomy, seven had graft reconstruction, one had an endarterectomy and 44 had no secondary intervention. There were 15 deaths, most from cardiovascular cause, although three, including two strokes, may have been complications of treatment. The median age of these patients was 73 years (range 63–90 years) compared with 68 years (range 29–94, $P = 0{\cdot}005$, Mann–Whitney) for the survivors. Eight patients had a major amputation either because there was no viable calf vessel after thrombolysis or after a failure of secondary intervention. There were six major bleeds, five from the arterial puncture site.
Conclusion: These results show a poor outcome in 23 per cent of patients treated for symptoms of claudication. This may be because the patients were progressing towards limb-threatening ischaemia at the time of treatment, thrombolysis caused calf vessel occlusion or because the lack of a definition for acute limb ischaemia has made classification of these patients difficult.

Vascular 019

An outcome audit of 99 consecutive thoracoscopic sympathectomies

A.D. Fox, J. Collin and L.J. Hands *University of Oxford, Nuffield Department of Surgery, John Radcliffe Hospital, Oxford*

Background: Thoracoscopic sympathectomy (TS) is an effective treatment for palmar hyperhidrosis but its role in axillary hyperhidrosis, digital vascular disease and causalgia is uncertain. We have reviewed our total experience of TS.
Method: All records of patients undergoing TS between January 1992 and July 1997 were analysed. Clinical indications, immediate and late outcomes and complications were recorded. Follow-up was performed for all patients by completion of a postal or telephone questionnaire.
Results: Ninety-nine thoracoscopic sympathectomies were performed in 60 patients. The indications were palmar hyperhidrosis (80), axillary hyperhidrosis (11), digital ischaemia (6), Raynaud's disease (1) and causalgia (1). Thirty-six females and 18 males (median age 28·8 years, range 15–48 years) underwent surgery for hyperhidrosis. All patients treated for palmar hyperhidrosis were initially cured. Surgery for axillary hyperhidrosis was technically successful in all but one case. Although axillary anhidrosis was not achieved in any patient, all who had successful surgery were satisfied that their symptoms were considerably ameliorated. Patients were discharged one day postoperatively except for one who required a chest drain. Compensatory sweating developed in 24 patients (21 trunkal, 6 gustatory, 5 perineal, 5 facial, 5 plantar and 3 axillary). Compensatory truncal sweating was most severe after bilateral sympathectomy. Complications occurred in eight patients (three pleuritic chest pain, two intercostobrachial neuralgia, one intercostal vessel haemorrhage, one arm stiffness and one spontaneously resolving pneumothorax). There were no eye signs of Horner's syndrome. All complications resolved without further intervention. Nine patients reported some return of palmar sweating but they considered this a better outcome than anhidrosis. Three patients developed recurrent palmar hyperhidrosis at 6, 15 and 21 months postoperatively. The patient with the 6-month recurrence underwent a second thoracoscopic sympathectomy without further recurrence at 2 years. Two patients treated for digital ischaemia have since died. The remaining patients did not improve following TS.
Conclusion: Thoracoscopic sympathectomy was initially successful in all cases of palmar hyperhidrosis and 91 per cent of hyperhidrotic axillae. The main adverse effect was compensatory sweating which was more common after bilateral sympathectomy. The recurrence rate for palmar hyperhidrosis was 5·4 per cent, but repeat sympathectomy was successful in the one case in which it was attempted. Other recently suggested therapies for palmar hyperhidrosis will need to match these cure rates.

Vascular 020

Duplex scanning is unnecessary in all patients with primary, non-recurrent varicose veins

P.J. Kent and M.J. Weston* *Departments of Vascular and Endovascular Surgery and *Radiology, St James's University Hospital, Leeds*

Background: Duplex scanning of all patients undergoing varicose vein surgery is controversial. The aims of this study were: (i) to compare the accuracy of hand-held Doppler (HHD) assessment with duplex scanning in patients with varicose veins; (ii) to assess the benefit of tourniquet testing; and (iii) to identify patients who may benefit from a policy of selective duplex scanning.
Method: Venous reflux was assessed using HHD with an 8 MHz probe immediately followed by duplex scanning in 72 patients with primary, previously untreated varicose veins (108 limbs).
Results: HHD accurately assessed saphenofemoral junction reflux (sensitivity 0·93, specificity 0·91, positive predictive value 0·96, negative predictive value 0·85) and long saphenous vein reflux (sensitivity 0·95, specificity 0·68, positive predictive value 0·91, negative predictive value 0·80). HHD assessment of saphenopopliteal junction (SPJ) reflux was less accurate (sensitivity 0·82, specificity 0·80, positive predictive value 0·43, negative predictive value 0·96), although the high negative predictive value indicated that absent SPJ reflux is assessed accurately using HHD. Tourniquet testing was not helpful.
Conclusion: Selective duplex scanning of limbs with suspected SPJ reflux, no identifiable site of reflux or posterior thigh perforator reflux on HHD (39 per cent of limbs), would have resulted in the appropriate surgical procedure being performed in 102 (94 per cent) limbs, excessive surgery in five (5 per cent) limbs and inadequate surgery in only one (1 per cent) limb. The use of selective criteria for duplex scanning would reduce the workload of the vascular laboratory without compromising patient care.

Vascular 021

Can we stop recurrent varicose veins? A prospective observational study

E.P.L. Turton, S. Richards, K.G. Mercer, D.C. Berridge, P.J. Kent, R.C. Kester and D.J.A. Scott *Department of Vascular Surgery, St James's University Hospital, Leeds*

Background: Accurate preoperative diagnosis and adequate surgery undoubtedly help to reduce but not eliminate recurrent varicose veins. Other factors are therefore also important. The aim of this study was to assess the influence of disease progression and accuracy of varicose vein surgery on duplex-derived evidence of incompetent veins.
Method: Sixty legs in 45 patients (median age 50, range 27–75 years) undergoing varicose vein surgery were assessed and followed-up in a prospective observational study. All patients had duplex ultrasound imaging of their leg at three time points: preoperatively, at 6 weeks postoperatively, and at 1 year postoperatively. Venous mapping of sites of incompetence was performed systematically for comparison at each time point.
Results: Surgery successfully abolished all sites of pre-existing reflux. The postoperative duplex scan at 6 weeks revealed that new sites of reflux, not identified preoperatively, had developed in 12 limbs. At 1 year the reflux seen in six of these patients had disappeared entirely. New reflux, not present at the 6 week postoperative scan, was demonstrated in a further five patients at 1 year.
Conclusion: Varicose vein surgery can alter the haemodynamics of venous return. This may contribute to new sites of venous incompetence in the early postoperative period; these may disappear spontaneously.

Vascular 022

An audit of current management of varicose veins

T.A. Lees, B.M.F. Ridler and T. Szymanska *On behalf of the Vascular Audit Committee, Great Britain & Ireland*

Background: This study aimed to evaluate current management of varicose veins by vascular surgeons.
Method: A questionnaire was sent to all 427 members of the Vascular Surgical Society.
Results: The response rate was 65 per cent, of whom 77 per cent were general surgeons with a vascular interest (Group A), 21 per cent were vascular only (Group B), and 2 per cent were non-vascular (Group C). Seventy-three per cent of respondents see varicose vein patients in a vascular or a dedicated venous clinic. The median (range) number of patients seen per week is five (0–78) and the waiting time to be seen is 12 (1–150) weeks. Three (0–12) varicose vein operations per week are performed of which 10 per cent (0–50 per cent) are for recurrence and 50 per cent (0–96 per cent) are day cases. Sixty-five per cent of surgeons use hand-held Doppler routinely in the assessment of varicose veins and 85 per cent use duplex scanning as their first line other investigation. Eighty-one per cent and 67 per cent perform synchronous bilateral surgery for long and short saphenous vein varicose veins, respectively. Day-case surgery is performed for primary long saphenous vein (LSV) varicose veins by 86 per cent, for unilateral recurrence by 51 per cent, and for primary bilateral varicose veins by 32 per cent. For primary LSV varicose veins 90 per cent perform saphenofemoral disconnection, 82 per cent stripping to the knee, 2 per cent stripping to the ankle and 95 per cent multiple avulsions. For recurrence associated with groin reflux 94 per cent perform groin re-exploration and 75 per cent strip a residual LSV. For recurrence associated with reflux in the popliteal fossa 91 per cent perform re-exploration of the popliteal fossa and 27 per cent strip a residual short saphenous vein. Thirty-five per cent do not stop any hormone therapy prior to surgery. Surgical practice was similar in Groups A and B. Sixty-eight per cent of respondents perform sclerotherapy for varicose veins on the NHS, predominantly for isolated small varicose veins and missed varicose veins following surgery.
Conclusion: The management of varicose veins by most vascular surgeons is similar. There remains a variety of practice in relation to hormone therapy and varicose vein surgery.

Vascular 023

An evaluation of pin stripping vs conventional stripping in the treatment of primary varicose veins: pilot study

M. Durkin, E.P.L. Turton, D.C. Berridge, D.J.A. Scott, P.J. Kent and R.C. Kester *St James's & Seacroft University NHS Trust Hospital*

Background: Stripping of the long saphenous vein (LSV) can be considered vital in the surgical treatment of primary varicose veins when valvular incompetence is present. Ensuring the high tie and stripping is accurate and effective can also prevent recurrence. Removal of the LSV can be achieved in a variety of different ways. This study is a comparison of two such methods. This study aimed to examine the efficacy of perforate invagination (PIN) stripping in comparison to conventional stripping in a prospective randomized trial.
Method: Eighty patients were recruited to undergo stripping of the LSV as indicated by their clinical need. They were randomized to PIN or conventional stripping with all other operative techniques remaining constant. Postoperatively all patients were followed-up for 1 week.

Results:

	Time to strip veins (min)	% vein stripped	Size of exit site (cm)	Area of bruising (cm^2)
Median (IQR)				
C (range)	5·57 (4·46–8·17)	89·64 (67·03–100)	0·55 (0·5–0·7)	91·5 (68–153)
P (range)	5·30 (4·41–9·38)	85·71 (52·48–100)	0·4 (0·35–0·5)	84 (54–167)
P level	0·736	0·496	0·0049	0·749

C = conventional; P = PIN.

Conclusion: There was no statistically significant difference in terms of speed and efficacy of use and morbidity from postoperative bruising between the PIN and conventional stripper. The PIN resulted in smaller exit wound which was statistically significant.

Vascular 024

Thromboembolism after varicose vein surgery

E.H. Streeter, T. Qureshi, M.R. Harvey and C.R.R. Corbett
The Princess Royal Hospital, Haywards Heath, West Sussex

Background: There are no clear guidelines for heparin prophylaxis in varicose vein surgery but there is a risk of litigation from a patient on the oral contraceptive pill (OCP) or hormone replacement therapy (HRT) who suffers a thromboembolic complication. The risk of thromboembolism is too low for a controlled trial to solve the question so practice varies according to individual prejudice.
Method: A database of 1185 patients (830 women: 355 men, mean age 49 years, range 16–83) who had varicose vein surgery over 12-years was reviewed.
Results: Deep vein thrombosis (DVT) occurred in six (5 men: 1 woman, mean age 59 years, range 48–66). One man had a non-fatal pulmonary embolism; one had a history of previous DVT; one suffered an axillary vein thrombosis. Male risk of DVT was 5/355 (1·4 per cent). The one woman with DVT was 66 years of age and not on HRT. Female risk of DVT was 1/830 (0·12 per cent). The sex difference was significant by χ^2 analysis ($P<0·02$). A subset of the last 181 women showed 13/89 (15 per cent) 'eligible' 20–49 year olds on the OCP, and 17/103 (17 per cent) 'eligible' 40–69 year olds on HRT. Overall no women on OCP/HRT suffered from thromboembolism, but only 16 per cent of this subset (30/188) were exposed to the risk.
Conclusion: We regard previous DVT as the highest risk factor and recommend Enoxaparin 40 mg subcutaneously for 8 days. Patients on OCP/HRT should receive heparin 5000u subcutaneously while in hospital (often only 1–2 doses), but the present evidence suggests male sex is a greater risk factor so we conclude that it may be simpler to give heparin to all patients, hoping that 1–2 doses will have an effect.

Vascular 025

A specialized community leg ulcer service: the Gloucestershire experience

A.S.K. Ghauri, M.R. Whyman, J.J. Earnshaw, B.P. Heather and K.R. Poskitt *Gloucestershire Vascular Group*

Background: This study evaluates healing and recurrence of chronic leg ulcers in East and West Gloucestershire before and after establishment of a specialized vascular-led community-based service in East Gloucestershire.
Method: In East Gloucestershire, outcome of a random sample of chronic leg ulcers ($n=100$) from 3 months before clinics was compared to that of consecutive limbs ($n=200$) subsequently managed in specialized clinics. West Gloucestershire was the control in this study with random samples of chronic leg ulcers ($n=100$) being compared from 3-month intervals before and after clinics had been established in neighbouring East Gloucestershire.
Results: The 24-week healing and 1-year recurrence rates of limbs with completed 12-month follow-up are summarized below:

	Before		After	
	East	West	East Clinics	West
Ulcerated limbs	100	100	200	100
Validated chronic leg ulcers	97	97	200	93
24-week healing	29 (30%)*	21 (22%)	135 (68%)*	26 (28%)
1-year recurrence	37/79 (47%)*	26/59 (44%)	26/114 (23%)*	20/58 (35%)

*$P<0·01$ (χ^2-test).

Conclusion: Chronically ulcerated limbs assessed, managed and followed in a specialized community service had improved in both healing and recurrence after 1 year.

Vascular 026

Calman, venous surgery and the vascular trainee

E.P.L. Turton, M. Whitely, D.C. Berridge and D.J.A. Scott
St James's & Seacroft University NHS Trust Hospital

Background: Venous surgical training has traditionally been the 'Cinderella' of vascular surgery. With the advent of Calman training and Vascular Surgical Society recommendations, we have audited the venous surgical experience of Vascular Trainees.
Methods: Questionnaires were sent to 90 vascular surgical trainees achieving a 77 per cent response rate ($n=69$).
Results: Twenty-eight (41 per cent) trainees had spent >12 months on a pure vascular firm, compared to 37 (54 per cent) on a general/vascular firm. While the majority had been trained in saphenofemoral junction ligation (91 per cent) and saphenopopliteal junction ligation (87 per cent), only 59 per cent used preoperative duplex and only 14·5 per cent preoperative venography. The use of newer techniques such as perforate invagination (PIN) stripping (42 per cent), Oesch hooks (39 per cent), or Muller hooks (22 per cent), were all comparatively low. Nineteen trainees (27·5 per cent) had not received training in the use of any hook devices in varicose vein surgery. Recurrent varicose vein surgery revealed further deficits. Thirty per cent of trainees had not received specific training in the lateral approach to a persistent saphenofemoral junction. This was even more marked for the superior (67 per cent) and medical approaches (81 per cent). Deep venous surgical training was sparse. The majority of trainees (75 per cent) had not received any training. Indeed only one operation was actually performed by a trainee. No formal training in sclerotherapy was received by 21 (30 per cent) of trainees, and 74 per cent ($n=51$) had not been trained in the use of microsclerotherapy techniques. Separating the trainees into those with greater or less than 12 months' experience on both general vascular and pure vascular firms reduced, but did not eliminate, these deficits.
Conclusion: Current training schedules do not cover the field of venous surgery adequately. Vascular specialists should aim for a broader venous surgical training, tailored to the trainees' experience on entry to their firm.

Vascular 027

The natural history of infrainguinal vein grafts performed for popliteal aneurysms

M.J. McCarthy, I.M. Loftus, A.R. Naylor, N.J.M. London, P.R.F. Bell and M.M. Thompson *Department of Surgery, Clinical Sciences Building, University of Leicester, Leicester*

Background: The treatment of choice for popliteal aneurysms is infrainguinal venous bypass grafting, however, no long-term follow-up studies of these grafts have previously been described. The aim of this study was

to establish the natural history of infrainguinal vein grafts that had been performed for popliteal aneurysms.
Method: Between 1988 and 1997, 351 infraguinal vein grafts were performed, 27 of these were for a popliteal aneurysm of 3 cm or more in diameter. Standard operative technique was Hunterian ligation of the aneurysm and bypass grafting using autologous vein. All grafts were included in a vein graft surveillance programme and data were collected from a surveillance database and case-note review.
Results: There was no difference in the sex, age and risk factor distribution between patients receiving vein grafts for popliteal aneurysm or occlusive disease. In patients grafted for popliteal aneurysm, the median follow up was 41 months (1–98 months). Six (22 per cent) grafts developed a significant stenosis (peak velocity ratio >2·5) within the first 6 months of follow-up; after this no further *de novo* or recurrent vein graft stenoses occurred. This group of patients had an overall lower incidence of vein graft stenosis than grafts performed for occlusive disease ($P<0{\cdot}038$). Subsequently, 12/27 (44 per cent) of the vein grafts developed spontaneous true aneurysms after a median of 30 months (7–84 months). Four of these reached 3 cm in diameter and had elective revisional surgery. The incidence of true aneurysm formation in this group was significantly higher than vein grafts for occlusive disease ($\chi^2 = 97{\cdot}3$, $P<0{\cdot}001$ with Yates continuity correction). Five-year cumulative primary, primary assisted and secondary patency rates were 58 per cent, 76 per cent and 82 per cent, respectively which are all higher than the rates for vein grafts for occlusive disease, 23 per cent, 52 per cent and 60 per cent, respectively (log rank test, $P = 0{\cdot}0128$, 0·058 and 0·0063).
Conclusion: Vein grafts performed for popliteal aneurysms had a lower incidence of vein graft stenosis but a significantly higher rate of spontaneous true aneurysm formation. Vein grafts performed on these patients should therefore be monitored in a surveillance programme indefinitely.

Vascular 028

Vein graft surveillance can stop after 1 year, but limb surveillance is for life

M.J. McCarthy, D. Olojugba, I.M. Loftus, A.R. Naylor, P.R.F. Bell and N.J.M. London *Department of Surgery, Clinical Sciences Building, University of Leicester, Leicester*

Background: It has been suggested that vein graft surveillance can be stopped after 1 year due to the low incidence of vein graft stenosis after this time. This approach may have important cost saving implications. Vein grafts that develop stenoses are at greater risk of developing further stenotic lesions and need to be monitored closely. The aim of this study was to establish whether surveillance could be stopped after 1 year in infrainguinal vein grafts that had not developed *de novo* arterial or vein graft lesions within that time period.
Method: Data were collected prospectively on 326 patients who had undergone 351 infrainguinal venous bypass grafts between 1988 and 1997. Vein graft surveillance occurred at 1, 3, 6, 9, 12 months and at 6-month intervals thereafter. Duplex imaging examined the vein graft and arterial inflow/run-off vessels in each limb. A significant vein graft stenosis was diagnosed when a peak systolic velocity ratio was greater than 2. Grafts that had not developed a significant stenosis during the first year of surveillance were investigated further to establish the incidence and risk of developing subsequent *de novo* stenotic lesions.
Results: One year cumulative limb salvage, patient survival, primary, primary assisted and secondary patencies were 81 per cent, 77 per cent, 44 per cent, 67 per cent and 81 per cent, respectively. One hundred and four (29·6 per cent) grafts developed a significant primary vein graft stenosis, 95 (91 per cent) of which occurred within 12 months. After 1 year, the average risk of developing a significant graft stenosis was 3 per cent per year. Sixty-nine grafted limbs developed arterial inflow/run-off stenoses that required intervention, but only 37 (54 per cent) occurred within the first year, after which, the average risk was 9 per cent per year. After 1 year, only 78 grafts/limbs could be identified that had not developed *de novo* vein graft/arterial inflow or run-off stenoses. Subsequently 17 (21·8 per cent) of these grafts went on to develop primary vein graft and/or arterial stenotic lesions that required intervention. The overall average risk was 9·5 per cent per year of developing a *de novo* vein graft or arterial stenosis in a limb.
Conclusion: The risk of developing a stenosis in a vein graft drops considerably after 1 year. However, *de novo* arterial lesions, that may threaten graft patency, occur at a rate of 9 per cent per year. Vein graft surveillance could stop at 1 year but the limb is still at risk of developing potentially graft-threatening arterial stenoses and therefore limbs that have undergone infrainguinal vein bypass grafting must continue to be monitored in a surveillance programme for life.

Vascular 029

Plasma homocysteine is an independent risk factor for vein graft stenosis

M. Mireskandari, M. Schachter, I.G.O. Timms, P. Sever and J.H.N. Wolfe *Regional Vascular Unit, St Mary's Hospital, London*

Background: This study investigated the association between hyperhomocysteinaemia and the development of stenosis in infrainguinal vein bypass grafts.
Method: Sixty-one patients, 62 limbs (44 men) with median age 72 years (range 35–95) undergoing femorodistal vein bypass were recruited. Fifty-eight per cent had surgery for critical limb ischaemia (CLI), 30 per cent for intermittent claudication (IC), 8 per cent for correction of asymptomatic vein graft stenosis (VGS), and 4 per cent for acute limb ischaemia (ALI). All patients underwent a 1-year graft surveillance programme. Fasting plasma total homocysteine (THC) levels together with other putative markers for development of vein graft stenosis (fibrinogen, lipid profile, and cotinine) were measured. Serum B12 and red cell folate (RCF) were measured as factors which mainly affect THC levels.
Results: After 12 months, 42 grafts were classified non-stenosed and 20 stenosed. Median THC levels were 9·5 µmol/ml (range 5·4–32·0) in the no-stenosis group and 14·4 µmol/ml (9·6–32·0) in the stenosis group ($P<0{\cdot}0001$, Mann–Whitney U-test). (Reference range for THC was 5·0–15·0 µmol/ml.) Median plasma fibrinogen levels were 2·85 mg/ml (1·8–6·6) in the no-stenosis group and 3·72 mg/ml (2·37–8·0) in the stenosis group ($P<0{\cdot}003$ Mann–Whitney U-test). Median RCF levels in the no-stenosis group were 284·0 µg/ml (118·5–649) and 197·5 µg/ml (96·0–591·0) in the stenosis group ($P<0{\cdot}04$ Mann–Whitney U-test). In this study serum B12, lipid profile and cotinine were not significantly associated with stenosis on univariate analysis.
Conclusion: Raised levels of THC are strongly associated with graft stenosis. Reduction of plasma THC by folate supplementation may prevent development of stenosis in at risk patients.

Vascular 030

Is acute normovolaemic haemodilution a useful adjunct to blood conservation in peripheral vascular surgery?

J.I. Spark, K.G. Mercer, I.C. Chetter, A. Lumb, L. Caldicott, D.J.A. Scott, D.C. Berridge and R.C. Kester *Department of Vascular and Endovascular Surgery and Anaesthesia, St James's University Hospital, Leeds*

Background: This study aimed to establish the extent to which acute normovolaemic haemodilution (ANH) can be applied to lower extremity peripheral vascular surgery as a blood conservation method to minimize patient exposure to homologous blood transfusion (HBT).
Method: Forty patients, 26 men and 14 women, with a median age of 68 years, undergoing elective femorodistal bypass for chronic critical ischaemia were recruited prospectively with an intention to avoid perioperative HBT. Recommended exclusion criteria were applied and transfusions were given in cases of large volume blood loss and symptomatic anaemia.
Results: Fifteen (37 per cent) of the patients were excluded preoperatively because of poor left ventricular function, anaemia or renal impairment and a further six because of a fall in haematocrit to less than 35 per cent due to colloid/crystalloid requirements before surgery. Median blood

loss was 1150 ml and median blood collected 1040 ml suggesting reasonable utility on the remaining patients in preventing HBT. Eleven patients, however, lost less than 650 ml and would have avoided HBT in any case. Two patients lost over 2·5 L and required intraoperative transfusion. Two of the remaining six patients suitable for ANH and with moderate blood loss (950–1400 ml) required transfusion in the immediate postoperative period due to symptomatic anaemia. Only four patients avoided exposure to HBT.
Conclusion: Preoperative co-morbidity and the variability of blood loss during peripheral vascular surgery combine to make the complex process of ANH of very modest value to the patient undergoing peripheral vascular surgery.

Vascular 031

A strategy for vascular services: testing the hypothesis

S. Arora*, J.H.N. Wolfe, J. Colin, S. Darke and S. Hargreaves*
**Department of Public Health, Kensington & Chelsea and Westminster Health Authority*

Background: The delivery of vascular services has been criticized and reorganization based upon a suggested population of 600 000, with the two underlying principles being that patients with vascular problems should be treated by surgeons with a vascular practice and that the surgeon should have a 1:4 rota. The aim of the study was to test the hypothesis in three disparate regions.
Method: North West Thames, Wessex and East Anglia were assessed for vascular operations/10 000 population and hospital activity for 1994/95 (Hospital Episode Statistics [HES]). Activity statistics were validated against unit audit in one hospital for each region. A surgeon from each hospital replied to a questionnaire regarding resources.
Results: There was little variation in the operations/10 000 between the three regions (range 4·55–4·99). All these regions had four units providing a service for more than their local population. In one region all these units were also performing more than 200 operations per year and more than 20 carotid endarterectomies per year, but in the other two regions only two units met these criteria. These four units (most of which are in district hospitals) could, between them, provide a service for 2 400 000, leaving the option for smaller units (based upon 300 000) to provide the service for geographically inaccessible areas. The HES activity had >90 per cent concordance with local audit in all regions and inadequate facilities were not related to low vascular throughput (questionnaire response rate >70 per cent in all regions). Four hospitals in one region and five hospitals in two regions performed <50 vascular operations per year and it might be advantageous to transfer these patients to another hospital.
Conclusion: With co-operation, a strategy based upon a smaller number of units providing full vascular cover throughout the year could be effective in all three regions studied.

UGI 010

Cost-effectiveness and quality of life in individuals undergoing treatment for oesophageal carcinoma

M.A. Farndon*, M.B. Clague and S.M. Griffin *The Oesophago-Gastric Cancer Unit and *Medical School, University of Newcastle upon Tyne, Newcastle upon Tyne*

Background: This study aimed to assess the relationship between clinical outcome, quality of life (QoL) and cost for the treatment modalities most commonly employed in the management of oesophageal carcinoma.

Method: Individuals diagnosed with oesophageal carcinoma in 1993 and managed in Newcastle upon Tyne were identified from Hospital Episode Statistics (HES) and the Northern Cancer Registry. Post-treatment interventions and outcome over a 3-year follow-up period were recorded. A cost-analysis profile was derived prospectively from a cohort of patients diagnosed over a 6-month period in 1996–97 who also underwent QoL asessment at monthly intervals over a 3-month period using the EORTC QLQ-C30 and OES24 disease-specific modules. Costs were calculated for radiotherapy (DXT), endoscopic and surgical procedures (accounting for staff and equipment costs in each case) as well as the cost of outpatient, in-patient and ITU attendance. Cost, QoL and survival were compared between treatment groups using the Mann–Whitney U and log rank tests.

Results: One hundred and thirty-nine individuals were identified retrospectively for the cost analysis and a further 51 recruited prospectively to assess quality of life. Survival was significantly better in patients treated by resection ($n=31$; median survival = 20 months) than for those receiving palliative treatment options ($n=108$; median survival = 6 months) ($P<0\cdot0001$). QoL measurements suggested significant improvement in reported dysphagia at 2 and 3 months post-treatment only for individuals who underwent resection although even this was at the expense of significant impairment of reported physical function and global health/QoL. Median cost was significantly greater in individuals who underwent resection (£8070) than for patients subjected to a palliative strategy (DXT = £4720, brachytherapy = £1790, laser = £3540, intubation = £2450, no treatment = £1390) ($P<0\cdot01$). When considering the median cost per month of life intubation and no intervention proved to be the most costly of the palliative options (£1125 and £971, respectively) compared with DXT at £693, brachytherapy at £364 and laser at £342. Resection (£457 per month) compared favourably for cost per month with these palliative options.

Conclusion: Surgical resection for oesophageal carcinoma results in the best survival and improvement in reported dysphagia. In view of the longer survival, costs are inherently greater in individuals undergoing resection; allowing for time, resection is at least as cost-effective as any other treatment modality.

UGI 011

Adjunctive chemoradiotherapy in oesophageal carcinoma: no increase in postoperative morbidity or mortality

E.D. Mulligan, T. Purcell, B. Dunne, M. Griffin, N. Noonan, D. Hollywood, N. Keeling, J.V. Reynolds and T.P.J. Hennessy *Departments of Surgery, Pathology and Gastroenterology, St James' Hospital, Dublin*

Background: The oncological benefit of preoperative chemo- and radiotherapy followed by surgery in oesophageal cancer has been established, with improved disease-free and overall survival reported. Assurances that this benefit is not at the cost of increased perioperative wound and septic complications as a result of the neoadjuvant therapies is required.

Method: We performed a detailed analysis of morbidity and mortality associated with these factors in randomized clinical trials of patients with oesophageal cancer receiving either neoadjuvant chemo- and radiotherapy prior to surgery or surgery alone. All complications that may be influenced by abnormal wound healing or immune function were recorded, including anastomotic leaks, organ failure, septicaemia and multiple organ failure.

Results:

	Multimodal ($n=104$)	Surgery only ($n=108$)
30-day mortality	11 (11%)	11 (10%)
Major complications	38 (37%)	44 (41%)
Number of complications	56	73
Pneumonia	22 (21%)	29 (27%)
Anastamotic leaks	10 (10%)	8 (7%)
Sepsis/multiple organ failure	4 (4%)	9 (8%)
Organ failure	9 (9%)	5 (5%)
Abdominal/thoracic abscess	6 (6%)	2 (2%)

Conclusion: There was no significant difference between groups in complications that may relate to preoperative wound healing and immune competence. Fears that a price may be paid in the perioperative period for the oncological efficacy of multimodal therapy were thus unfounded in these randomized studies.

UGI 012

Conservative management of perforated duodenal ulcer: continuing audit and current guidelines

C. Marshall, P. Ramaswamy, F.G. Bergin, I.L. Rosenberg and D.J. Leaper *North Tees General Hospital, Stockton-on-Tees, Cleveland*

Background: This study aimed to establish a protocol for conservative management of perforated duodenal ulcer (DU) with a continuing audit of the best practice guidelines.

Method: Thirty-six patients admitted between January 1991 and June 1997 with a perforated DU were treated conservatively according to protocol. Twenty further patients were excluded and treated operatively because they had generalized or deteriorating abdominal signs, a history of more than 24 h or were on antacid therapy. According to protocol all conservatively managed patients had a nasogastric tube and intravenous fluids, antibiotics and antacid therapy. Chest x-ray and gastrograffin confirmation of perforation were initially mandatory with discharge on antacid therapy and 6-week endoscopy.

Results: Of the 36 conservatively managed patients, 31 (86 per cent) had a history of less than 24 h; 35 (97 per cent) had a successfully placed nasogastric tube; antibiotics were given to 29 (81 per cent) and intravenous antacids to 30 (83 per cent); 34 (94 per cent) had an erect chest x-ray but only 16 (44 per cent) had a gastrograffin meal (five of which confirmed perforation). However, only 10 (25 per cent) had thromboembolic (DVT) stockings prophylaxis and 14 (39 per cent) subcutaneous heparin. Five patients failed conservative management and there were five complications. Only 19 (53 per cent) had follow-up gastroscopy which confirmed two gastric cancers.

Conclusion: We have found that perforated DU can be treated successfully and conservatively with a protocol that should be strictly followed. Audit reviews have strengthened the need for follow-up gastroscopy and DVT prophylaxis but dispensed with the need for gastrograffin confirmation and central venous monitoring.

UGI 013

The use of photodynamic therapy in the treatment of dysplastic Barrett's oesophagus

R. Ackroyd, M.F. Davis*, T.J. Stephenson†, N.J. Brown, C.J. Stoddard and M.W.R. Reed *Departments of Surgery, *Medical Physics, and †Histopathology, Royal Hallamshire Hospital, Sheffield*

Background: Photodynamic therapy (PDT) is a form of cancer treatment in which cell damage is achieved by the action of light on a photosensitizing agent. The aim of this study was to assess the value of PDT in the treatment of Barrett's oesophagus with low-grade dysplasia.
Method: Forty patients with biopsy-proven dysplastic Barrett's oesophagus were treated with PDT. All patients were given the photosensitizer aminolaevulinic acid (ALA) orally at a dose of 30 mg/kg. Four hours later, patients underwent endoscopy and administration of green laser light (514 nm) at a power density of 120 mW/cm^2 for 500 seconds (total energy 60 J). All treatments were performed under propofol sedation as day cases. All patients continued treatment with omeprazole 20 mg daily. Endoscopy and biopsies were repeated at 1 and 6 months, to assess the effect of treatment.
Results: A macroscopic response was seen in 33 out of 40 patients, with a median decrease in columnar epithelial area of 30 (range 0–90) per cent. Post-treatment biopsies showed no evidence of dysplasia in 39 out of 40 patients, with low-grade dysplasia remaining in one case. No significant side-effects were observed in any patient.
Conclusion: This study demonstrates that ALA-induced PDT provides safe and effective ablation therapy for Barrett's oesophagus. Further studies are required to increase the efficacy of this form of treatment.

UGI 014

Preoperative staging of upper gastrointestinal malignancy by endoluminal ultrasound

G.V. Miller, S.P.L. Dexter, C. Roberts, B.M. Dobbins, J.B. Davies, I.G. Martin, H.M. Sue Ling, D. Johnston and K.M. Harris *Departments of Surgery and Radiology and the Centre for Digestive Diseases, Leeds General Infirmary, Leeds*

Background: Accurate preoperative staging is essential in planning rational treatment approaches to upper gastrointestinal malignancy. Endoluminal ultrasound (EUS) has been reported to improve the accuracy of preoperative staging of these tumours and we have evaluated this technique since its introduction to this unit.
Method: Prospective evaluation of 59 patients (43 gastric and 16 oesophageal carcinoma; 41 men and 18 women) who underwent preoperative staging with EUS between May 1996 and October 1997. In all cases histological confirmation of disease stage was achieved and no patients received neoadjuvant therapy. Surgical treatment comprised 54 resections, four staging laparoscopy and biopsy and one open and close laparotomy. Preoperative evaluation by EUS was incomplete or impossible in five patients leaving 54 patients (41 gastric and 13 oesophageal carcinoma) for comparison of individual components of preoperative and final histological stage (1987 TNM staging).
Results: In 55 patients with upper gastrointestinal malignancy, EUS predicted the final histological T stage in 40 of 54 patients (accuracy 74 per cent) and the final histological N stage in 37 of 54 patients (accuracy 69 per cent).

	Gastric carcinoma ($n=41$)			Oesophageal carcinoma ($n=13$)	
	T1 & T2	T3 & T4		T1 & T2	T3 & T4
Sensitivity	73%	68%		88%	80%
Specificity	68%	73%		80%	83%
	N0	N1	N2	N0	N1
Sensitivity	100%	20%	56%	86%	83%
Specificity	65%	90%	87%	83%	86%

Conclusion: EUS is of value in preoperative staging of upper gastrointestinal malignancy, allowing correct identification of those patients who may benefit from neoadjuvant therapy prior to surgical resection.

UGI 015

Surgical outcome for vertical-banded gastroplasty for morbid obesity

K.M. Grundy, P.A. Davis, D.J. Corless, A. Qayyum and C. Wastell *Department of Academic Surgery, Chelsea & Westminster Hospital, London*

Background: The aim of this study was to determine the outcome of vertical-banded gastroplasties (VBG) for morbid obesity.
Method: One hundred consecutive gastroplasties were carried out on 19 men and 81 women between 1982 and 1997. A questionnaire was sent to all patients to establish their current weight and quality of life using specific questions related to lifestyle.
Results: The median preoperative weight was 133·6 (range 91·9–224) kg with a median body mass index (BMI) of 49 (32–76) which reduced postoperatively to a median weight of 108·2 (73–254) kg and a median BMI of 38 (27–81). There was one operative death caused by respiratory failure. The median follow-up time was 3·06 years (0–15·3). Of the 96 returned questionnaires, 85 per cent had lost weight, 15 per cent had gained weight since the operation. The quality of life questions showed that 74 per cent of patients considered their self esteem/confidence had improved as a result of the operation, with 26 per cent improving their employment situation. Seventy-two per cent consider the operation had helped control their weight and had altered their eating and exercise habits. Eleven patients (11 per cent) who lost weight considered the operation to have failed.
Conclusion: VBG represents a reliable and safe surgical option for patients in whom all other methods to control weight has failed: 85 per cent of patients lost weight, 72 per cent indicated an improvement in their quality of life.

UGI 016

Nurse practitioner for postoperative review of patients following oesophagectomy

J.M. Richardson, M. Harkin, J. Wayman, S.A. Raimes and S.M. Griffin *The Oesophago-Gastric Cancer Unit, Newcastle General Hospital, Newcastle upon Tyne*

Background: Following an initial audit of the post-discharge needs of patients undergoing subtotal oesophagectomy for cancer, a hospital-based, community liaison nurse practitioner role was implemented. The purpose of this audit was to assess the impact of instituting this change and its potential for altering the nature of postoperative follow-up for patients.
Methods: Patients who had undergone subtotal oesophagectomy were visited at home within 6 weeks of discharge for informal interview. Thereafter, repeat visits were at the discretion of the patient and nurse practitioner. Patients were encouraged to contact the nurse practitioner if problems occurred between routine 3-monthly outpatient appointments. Quantitative assessment was made by comparing the actions made as a result of nurse practitioner contact with those made as a result of consultant outpatient attendance. Qualitative assessment was made by interview and questionnaire survey of patients and their relatives.
Results: Over a 12-month period, 97 outpatient attendances were recorded compared to 85 home visits by the nurse practitioner. Twenty-two (26 per cent) of the nurse practitioner visits resulted in an intervention (most commonly endoscopy and dilatation of benign anastomotic stricture) compared with only five (5 per cent) of clinic attendances (χ^2 = 15·53 1 df; $P<0.0001$). There were no emeregency admissions of this group of patients via an accident and emergency department or GPs in this period. Thirty-five of 40 patients responded to a questionnaire survey, all of

whom supported the nurse practitioner visits. A key-word analysis of patient interviews and questionnaire responses highlighted 'support', 'expert advice', 'invaluable link', 'comfort', 'understanding' and 'reassurance' and descriptions such as 'invaluable link between hospital, community services and family' and 'its good to know that (she) is there to ring at anytime'.

Conclusion: The role of a hospital-based nurse practitioner is strongly supported by patients treated for oesophageal cancer. This facility is generally the preferred route of contact for patients with oesophageal cancer and avoids delay or unnecessary use of emergency routes.

UGI 017

Adenocarcinoma of the oesophago-gastric junction in the Northern and Yorkshire region 1984–1993

J. Wayman, S. Dresner, D. Forman*, S.A. Raimes and S.M. Griffin *The Oesophago-Gastric Cancer Unit, Newcastle upon Tyne and *Northern and Yorkshire Cancer Registry and Information Service, Leeds*

Background: Previous studies have demonstrated marked changes in the incidence of subsites of gastric and oesophageal cancer. The aim of this study was to identify whether this trend has continued in a large UK cancer registry and to evaluate the degree of misclassification under the existing system.

Method: The recently amalgamated Northern and Yorkshire Cancer registry was interrogated for all cases of oesophageal and gastric cancer occurring between 1984 to 1993. Data of year of registration, subsite (according to ICD 10 codes 1500–1509 and 1510–1519), histology, sex and age were recorded. Statistical analysis was performed using Spearman's rank correlation, χ^2- and t-tests.

Results: 22 300 cases were identified from an estimated population of 6·7 million. Overall the age-adjusted annual incidence of oesophago-gastric cancer fell from 36·2 to 30·1 per 100 000 in the 10-year period ($P<0{\cdot}001$). Oesophageal cancer increased from 9·22 to 10 per 100 000 ($P<0{\cdot}05$) due largely to the increased incidence of adenocarcinoma of the lower oesophagus (IGCA [International Gastric Cancer Association classification] Type 1 junctional cancers). The incidence of gastric cancer fell from 27 to 20·2 per 100 000 ($P<0{\cdot}05$). Cancer diagnosed at pyloric, antral, lesser curve, greater curve, body and fundus subsites all significantly fell in incidence ($P<0{\cdot}001$). The incidence of adenocarcinoma of the gastric cardia (IGCA Type 2 junctional cancers) did not significantly change although it increased in proportion from 34 per cent (1984/5) to 55 per cent (1992/3) of all gastric cancers (χ^2 = 11·962 4 df; $P<0{\cdot}05$). Throughout the 10-year period, the majority of cases of oesophageal (70·4 per cent) and gastric cancer (71 per cent) were recorded without any information about subsite.

Conclusion: Although the trends towards an increasing proportion of cancers at the oesophago-gastric junction reported in earlier studies have been confirmed in this study, the high incidence of imprecise subsite reporting must put the conclusions of this and other similar cancer registry studies in some doubt. Cancer registration must recognize 'junctional cancers' as distinct from other gastric and oesophageal subsites in order to monitor accurately the increase in this distinct group of oesophago-gastric cancers in subsequent studies.

UGI 018

The impact of a high dependency bleeding unit on surgical outcome in patients with bleeding peptic ulcer

M. Khan, J. Masson, A. Fraser, K.G.M. Park and N.A.G. Mowat *Department of Gastroenterology and Surgery, Aberdeen Royal Infirmary, Foresterhill, Aberdeen*

Background: The aim of this study was to determine the impact of a bleeding unit, with pre-set protocols on transfusion and surgical referral, on rates of surgery and surgical mortality in patients with bleeding peptic ulcers.

Method: Between October 1991 and October 1994 all patients with a suspected gastrointestinal bleed were admitted to a six-bedded bleeding unit serving a population of approximately 500 000. Patients were transfused per protocol until haemodynamically stable and thereafter endoscopy performed. Transfusions of greater than 4 units and significant re-bleeds were the principal indications for surgery.

Results: Six hundred and ninety-seven patients were found to be bleeding from peptic ulcers (duodenal ulcer 446, gastric ulcer 236 and stomal ulcer 15). Of these, 124 patients required emergency surgery (18 per cent). The commonest procedure undertaken was under-running of the ulcer and a truncal vagotomy and pyloroplasty ($n=68$) but simple under-running was performed in 13 and partial gastrectomy in 31. The operating surgeon was a consultant in 67 per cent and a senior registrar in 30 per cent of cases. The overall mortality for bleeding peptic ulcers was 5·3 per cent and the surgical 30-day mortality was 10 per cent. In all cases this was associated with severe co-morbid disease. The mean age of the patients who died was 80 years (range 68–90 years).

Conclusion: The low overall mortality and low surgical mortality seen in this unselected group of patients with bleeding peptic ulcers relates to aggressive resuscitation and diagnosis with early surgical referral when appropriate. These conditions are readily established within a specialized gastrointestinal bleeding unit.

UGI 019

The detection of response to chemotherapy using positron emission tomography in patients with oesophageal and gastric cancer

G.W. Couper, D. McAteer, F. Wallis, M. Norton, A. Welsh, M. Nicolson, P. Sharp, F. Gilbert and K.G.M. Park *Departments of Surgery, Oncology, Radiology and Bio-Medical Physics, University of Aberdeen, Aberdeen, Scotland*

Background: This study aimed to determine whether glucose metabolism, detected by fluorodeoxy-D-glucose (FDG) positron emission tomography (PET), was predictive of response to chemotherapy in patients with gastro-oesophageal cancers.

Method: Twelve patients with tumours of the gastro-oesophageal region were imaged with FDG-PET prior to commencing and following two cycles of chemotherapy. FDG uptake in tumours was quantified by Patlak analysis allowing comparison of the two scans. The images were compared with endoscopic, computed tomography (CT) and clinical evaluation of response to treatment.

Result: Changes in FDG uptake from the first to the second PET images ranged from a 15 per cent increase in activity to a 77 per cent decrease in activity. In 6/12 patients there was a decreased tumour FDG uptake following chemotherapy which corresponded with clinical and endoscopic evidence of response. In four of these cases there was also CT evidence of >50 per cent reduction in the tumour size. Of the six patients who had PET evidence of response, five underwent resection; two of these patients with stage III disease survived 12 and 20 months postoperatively, three remain disease free at 6–18 months follow-up. A further patient with liver metastases who responded is alive at 10 months. In six patients PET indicated either no change in FDG uptake or an increased uptake suggesting progressive disease. Five of these patients have developed recurrent disease within 6 months of treatment (two have died at 6 and 7 months). One patient with a recurrent tumour which remained stable on PET is alive at 9 months.

Conclusion: This study has shown that PET scanning may be able to detect response to chemotherapy in patients with gastro-oesophageal malignancy. An accurate means of determining response to preoperative chemotherapy could allow better patient targeting, i.e. selection of responders to continue with a full course of chemotherapy or of non-responders to abandon chemotherapy.

UGI 020

Preoperative manometric assessment of oesophageal dysmotility does not correlate with poor outcome after laparoscopic Nissen fundoplication

I.J. Beckingham*, A.K. Cariem†, J.A. Louw†, M. Callanan and P.C. Bornman **Department of Surgery, Nottingham, and †Departments of Surgical & Medical Gastroenterology, Groote Schuur Hospital, University of Cape Town, South Africa*

Background: Oesophageal dysmotility has been regarded as a contraindication to Nissen fundoplication because of concern over postoperative dysphagia. There is, however, little published data to support this conjecture and the aim of this study was to determine the outcome of patients with normal motility and dysmotility undergoing laparoscopic Nissen fundoplication.
Method: A single centre prospective cohort study with 1-year follow-up, using dysphagia as the main outcome variable.
Results: Of 81 patients with preoperative manometry who underwent laparoscopic surgery, 48 had normal motility and 33 had oesophageal dysmotility (defined as percentage peristalsis, using 10 wet swallows, of ≤50 per cent and/or a mean distal pressure of <40 mmHg). Dysphagia was present preoperatively in 14/48 of patients with normal motility and 15/33 of the dysmotility group ($P=0·2$). At 3-month follow-up, new or worse dysphagia was present in 13/48 of the normal group and 4/33 of the dysmotility group ($P=0·17$). At 1 year the incidence of dysphagia was 6/48 (12 per cent) in the normal group and 5/33 (15 per cent) in the dysmotility group ($P=0·9$).
Conclusion: Preoperative manometric assessment of oesophageal motility does not correlate with postoperative outcome. Oesophageal dysmotility should not be regarded as a contraindication to laparoscopic Nissen fundoplication.

UGI 021

Review of a 13-year surveillance programme for columnar lined oesophagus

K. Bani-Hani, H. Sue-Ling, D. Johnston and I.G. Martin
Academic Department of Surgery, Centre for Digestive Diseases, General Infirmary at Leeds, Leeds

Background: The aim of this study was to determine the incidence of adenocarcinoma (ADC) in columnar lined oesophagus (CLO) and to review our surveillance programme, because although the risk of cancer is well established, the magnitude of this risk is still controversial.
Method: Records of all patients with histologically confirmed CLO in our 13-year surveillance programme were examined retrospectively.
Results: A total of 357 patients out of 597 patients with CLO, entered a yearly endoscopy and biopsy surveillance programme. After a mean follow-up of 43 months, 12 patients, all with specialized epithelium, developed ADC (11 males), an incidence for males of 1 cancer per 67 patient-years and for females 1 cancer per 533 patient-years follow-up ($P<0·01$).
Conclusion: While the role of screening patients with CLO remains controversial, on the basis of this data there is no doubt that it is justified in male patients with specialized epithelium.

UGI 022

Lower oesophageal sphincter incompetence: a major component in gastro-oesophageal reflux disease

G.J.M. Tervit, D.J. Bowery, E. Kenyon, H. McKirdy, G.W.B. Clark and P.D. Carey *Department of Surgery, University of Wales College of Medicine, Cardiff*

Background: It is argued that in patients with significant acid reflux, manometric evaluation of the lower oesophageal sphincter (LOS) does not always reflect the severity of reflux or oesophagitis. In order to determine the relevance of stationary manometry, 77 patients referred for manometry and 24-h acid profile were compared with respect to their pH profile after manometric evaluation of the LOS.
Method: The 77 patients underwent stationary oesophageal manometry with a water perfused five-channel catheter. Sphincter pressure was recorded at the respiratory inversion point. An incompetent sphincter was defined by a mean resting pressure of <6 mmHg, an overall length of <2 cm, an abdominal length of <1 cm or any combination of these. pH monitoring was with an antimony electrode 5 cm above the LOS. Reflux disease defined as a DeMeester score of >14·8. Statistical analysis was by the Kruskal–Wallis test.
Results: Three groups were defined; 54 patients had a normal sphincter, of these 21 had no evidence of reflux (controls) and 33 had reflux disease (NR), 23 patients had defective sphincters and reflux disease (AR). The 24-h pH profile and the prevalence of endoscopic oesophageal injury were then compared between the groups.

	% time pH<4	% time upright reflux	% time supine reflux	Post-prandial events	Barrett's/ oeso-phagitis
Control	1·1 (0–1·5)	1·3 (0–2·6)	0 (0–0·2)	4 (0–8)	7%
NR	8* (6·0–11·9)	12* (8·9–16)	6·7* (0·2–8·2)	37* (14·9–37·5)	48%
AR	18*†(12·9–24)	16·6*†(7·1–26·2)	14·1*†(5·7–31·8)	18·5*†(9·5–37)	67%

Values are expressed as medians (IQR). $^*P<0·01$ vs controls, $^†P<0·01$ vs NR.

Conclusion: Patients with gastro-oesophageal reflux disease with mechanically defective LOS have the highest levels of oesophageal acid exposure. Compared with refluxers with good sphincters they are more likely to have supine reflux and the highest frequency of oesophagitis/ Barrett's and so are ideal candidates for anti-reflux surgery aimed at restoring normal sphincter function.

UGI 023

A comparative study of the presentation and outcome of adenocarcinoma and squamous cell carcinoma of the oesophagus

S. Dresner, J. Wayman, D.M. O'Hanlon, D. Karat, S.A. Raimes and S.M. Griffin *The Oesophago-Gastric Cancer Unit, Newcastle General Hospital, Newcastle upon Tyne*

Background: The aim of this study was to compare the clinical, pathological and prognostic characteristics of adenocarcinoma (ACA) and squamous cell carcinoma (SCC) of the oesophagus.
Method: Data were collected prospectively from patients with a histological diagnosis of oesophageal cancer between 1989 and 1996. Details of clinical presentation, endoscopic and pathological features, treatment and survival were compared between patients with ACA and SCC. Statistical analysis was performed using χ^2-squared, t-test and log-rank test.
Results: Three hundred and eighteen patients were studied (ACA = 172; SCC = 122). The male:female ratio was higher in patients with ACA (3·53:1 cf. 1·22:1; $P<0·001$). The mean age at presentation was no different [ACA = 66·33 (0·759) cf. SCC = 66·67 (1·116)]. Dysphagia was a more common presenting symptom in patients with SCC than ACA (115/122 cf. 143/172; $P=0·002$) and patients with ACA tended to have lower grades of dysphagia at presentation ($P=0·006$). A greater proportion of patients with ACA have had previous gastric surgery (36/171 vs 8/122; $P=0·0006$). A higher proportion of patients with ACA had a history of proton pump inhibitor ingestion prior to diagnosis (52/171 vs 15/121; $P=0·0003$). Smoking and alcohol intake were similarly common in both groups of patients. There was no difference in stage of disease at presentation. A similar proportion of patients of each histological subtype were treated by resection [55 per cent (ACA) cf 43 per cent (SCC)]. Survival was no different between histological subtypes overall and stage for stage according to treatment policy.
Conclusion: ACA shows a greater male predominance and is less likely to present with dysphagia than SCC. The higher incidence of previous gastric surgery and prior prescription of proton pump inhibitors suggest a different aetiology for adenocarcinoma of the oesophagus.

UGI 024

Survival following Ivor–Lewis oesophagectomy with two-field lymph node dissection

D.M. O'Hanlon, J. Wayman, D. Karat, S.A. Raimes and S.M. Griffin *The Oesophago-Gastric Cancer Unit, Newcastle General Hospital, Newcastle upon Tyne*

Background: Patients with oesophageal carcinoma present frequently with advanced disease and only surgery offers the best palliation and the best chance of cure. The aim of this study was to examine survival and recurrence following a two-stage Ivor–Lewis oesophagectomy with two-field lymphadenectomy.

Method: A consecutive series of 107 patients undergoing oesophagectomy in this hospital under the care of one surgeon was analysed. A proforma was completed, data was collected prospectively and entered on to a database. All patients underwent a preoperative assessment to evaluate patient fitness and tumour resectability.

Results: The mean age (range) of patients was 62·1 years (40–77 years) and 80 (74·8 per cent) were men. Sixty-three patients (58·9 per cent) had adenocarcinoma and 39 (36·4 per cent) had squamous cell carcinomas. Three patients died in hospital following surgery giving an in-hospital mortality of 2·8 per cent. Patients were subdivided according to stage and the 2-year, 5-year and median survival are given below:

Stage	2-year survival %	5-year survival %	Median survival (months)
Carcinoma *in situ*	100	100	>48
I	82*	82*	>48
IIa	66	43	39
IIb	69	27	28
III	25	19	17
Node negative	70	52	>48
Node positive	35	19	19
Overall	52	35	26

*100% if 30-day mortality excluded.

Conclusion: Excellent survival can be achieved following surgery for oesophageal carcinoma and surgery with or without neo-adjuvant chemoradiotherapy is the gold standard for treatment of oesophageal cancer.

General 001

The surgical impact of adhesions

M.S. Wilson[1], H. Ellis[2], M.C. Parker[3], D. Menzies[4], B.J. Moran[5], J.N. Thompson[6], A. McGuire[7], F. O'Brien[8], S. Buchan[9] and A.M. Crowe[9] [1]*Royal Preston Hospital, Lancashire,* [2]*United Medical and Dental Schools, London,* [3]*Joyce Green Hospital, Kent,* [4]*Colchester General Hospital, Essex,* [5]*North Hampshire Hospital, Hampshire,* [6]*Chelsea and Westminster Hospital, London,* [7]*City University, London,* [8]*Information and Statistics Division, NHS in Scotland,* [9]*Strategen Ltd, Disease and Therapy Management*

Background: This study aimed to determine the long-term morbidity associated with postoperative adhesions following open abdominal and pelvic surgery.
Method: Scotland's NHS hospital admissions are recorded by the Scottish Patient Record Linkage system. This system allows detailed analysis of hospital activity throughout Scotland including follow-up of individual patients. It has sophisticated accuracy checks to ensure the quality and totality of the dataset. The total number of individuals who underwent an open abdominal or pelvic procedure in 1986 was defined. Disease (ICD9) and procedure (OPCS3/4) codes for adhesion-related problems or reoperations that might be complicated by the presence of adhesions were identified. For the purposes of the study only codes for directly related adhesions complications were selected (e.g. small bowel obstruction and adhesiolysis). These were then used to identify those individuals who had admissions and possibly procedures directly related to postoperative adhesions over the next 10 years. The study was steered by a multidisciplinary panel of surgeons, gynaecologists and health economists.
Results: In 1986, a total of 29 788 patients had surgery in Scotland that was considered likely to cause adhesions. During the next 10 years 10 325 individuals (34·7 per cent) required one or more readmissions for surgical or medical treatment for conditions either related to adhesions or involving a reoperation which could be complicated by adhesions. 21 342 surgical or medical readmissions were identified in these patients; 1169 (5·5 per cent) of these admissions were identified as a direct result of abdominal or pelvic adhesions (3·9 per cent of all initial operations). This constituted a large clinical burden throughout the study period. Considerable variation in the rates of readmission was seen when the site of the initial surgical procedure was analysed.

			Readmissions directly attributable to adhesions		
Site of initial surgery	No. patients	Total no. readmissions	Total number	% of all readmissions	% of initial surgery
Lower GI	12 585	8861	627	7·1	5·0
Upper GI and 'other abdominal'	8714	7048	321	4·6	3·7
Gynaecological	8489	5433	221	4·1	2·6
Total	29 788	21 342	1169	5·5	3·9

Conclusion: The study provides the first epidemiological assessment of post-surgical adhesions and using an extremely conservative view, the impact of adhesions, both medical and surgical, is considerable, with 5·5 per cent of readmissions over a 10-year period directly attributable to adhesions. The full impact of adhesions, including their effect on subsequent surgery, is likely to be considerably greater and extensive research is in progress to investigate the burden further.

General 002

External oblique aponeurosis nerve entrapment as a cause of groin pain in the athlete

P. Ziprin and M.E. Foster *East Glamorgan Hospital, Pontypridd, East Glamorgan*

Background: Groin pain in sportsmen is a common diagnostic and management problem. We describe the findings and results of surgical exploration in 25 athletes.
Method: All patients were male, age range 20–35 years, and had had failed conservative management. All groins were explored via an inguinal incision. The patients were reviewed with regards to pain, function, and their own subjective assessment of the operation.
Results: Nineteen cases were unilateral and six were bilateral. In one patient an occult inguinal hernia was found, and one patient had a patent processus vaginalis. In all patients defects were found in the external oblique aponeurosis through which neurovascular bundles, which contained the terminal branches of the iliohypogastric nerve, passed. These defects were closed after division of the neurovascular bundles. The mean delay from the time of injury to referral was 29·3 weeks (range 4–79 weeks) during which each patient had unsuccessful conservative treatment. The mean follow-up for the patients was 20·6 months (7–56 months). Postoperatively no pain or only mild pain was experienced in 28 groins and the function had improved in all. Eighty-eight per cent of the patients described the operation result as good or excellent with all of the patients returning to full sporting activities within 11·6 weeks (range 4–20).
Conclusion: We believe that athletes' groin pain may be due to nerve entrapment in the lower part of the external oblique aponeurosis. We suggest that an awareness of the symptomatology and the benefits of surgery may lead to early surgical exploration and, therefore, early resumption of sporting activities.

General 003

Driver reflex times following open and endoscopic 'tension free' hernia repair

D.M. Wright, M.G. Hall*, C.R. Paterson and P.J. O'Dwyer
University Department of Surgery, Western Infirmary, and
**Department of Physiology, University of Glasgow, Glasgow*

Background: One of the most frequently asked questions following inguinal hernia repair is when the patient can return to driving a car. The current recommendation, based on a study of plication darn-type repair, is that the patient should not drive for 10 days.
Method: The aim of this study was to measure both hand and foot reaction times in a car simulator. Sixty-four patients randomized to open and endoscopic 'tension-free' hernia repair were studied. The reaction times were measured preoperatively and at 1, 3 and 6 days postoperatively.
Results: There was no difference between the groups in age, sex or site of hernia. No significant difference was found in hand reaction times between the groups on each of the postoperative days. The mean changes in foot reaction times are shown below in milliseconds and are expressed as positive (slower) or negative (faster) in relation to preoperative values.

Day	Open	Endoscopic	*P* value
1	30·6	–4·2	0·01
3	32·5	–10·4	0·003
6	–7·0	–16·9	0·27

Conclusion: The significant decrease in reaction times in the open group at days 1 and 3 appears to be due to a combination of a delay in response caused by analgesics and an increase in the transfer time due to discomfort from the operation site. These results provide objective evidence that endoscopic hernia repair allows a faster return to normal activities than open 'tension-free' repair. Patients undergoing open or endoscopic 'tension-free' inguinal hernia repair can return to driving within 1 week of operation.

General 004

Dynamic magnetic resonance imaging: a new diagnostic modality for groin pain?

S.W.T. Gould, G. Lamb, N. Vaughan, W. Gedroyc and A. Darzi *Academic Surgical Unit and Interventional MRI Unit, Imperial College School of Medicine at St Mary's Hospital, London*

Background: Existing diagnostic modalities are either invasive or insufficiently sensitive to distinguish reliably occult inguinal hernia from musculotendinous injury as a cause of groin pain. This may result in a high negative surgical exploration rate. The aim of this study was to develop a non-invasive dynamic magnetic resonance (MR) technique to differentiate these lesions.
Method: Eleven patients (nine men, two women; age range 29–73 years; median age 43 years) were studied in a 0·5 T General Electric Signa SP interventional magnetic resonance (IMR) unit. One patient had a persistent painful groin swelling 3 months after open mesh hernia repair and 10 presented with groin pain without physical signs (one had had a previous inguinal hernia repair). Static imaging [T1 fast spin echo (FSE), fast gradient recalled (FSPGR) and short tau inversion recovery (STIR)] was performed supine for detailed anatomical examination and differentiation of structural from inflammatory lesions. Dynamic real time imaging (FSPGR, acquisition time 2 s) was then performed supine, kneeling at rest and during a Valsalva manoeuvre to assess inguinal canal integrity with muscular exertion in a physiological position.
Results: All patients tolerated the procedure. In the 10 without physical signs, imaging revealed one indirect sac (male, 30 years) and one recurrent direct sac (male, 60 years). Defects in the fascia transversalis were clearly delineated and the sacs could be seen herniating through these defects on Valsalva manoeuvre. STIR images in these cases were normal. Seven others demonstrated high signal on STIR images in the posterior rectus muscle, conjoint tendon or at the pubic insertion of the inguinal ligament. No hernial defect was demonstrated in these cases. These findings were consistent with musculotendinous injury. No abnormality was demonstrated in the final case with groin pain (male, 24 years). The lesion in the patient with persistent groin pain and swelling after previous repair was demonstrated to be a cord haematoma and not a recurrent hernia by high signal on T2 and STIR imaging.
Conclusion: This study has demonstrated that dynamic MR imaging in physiological positions can detect and differentiate occult groin hernia from musculotendinous injury. This may reduce the high negative surgical exploration rate for such patients in the future.

General 005

Shouldice inguinal hernia repair revisited: a prospective, randomized trial of non-absorbable versus absorbable suture

F.G. Bergin, H.B. Devlin and E.L. Gilliland *North Tees General Hospital, Stockton-on-Tees, Cleveland*

Background: This study aimed to assess the efficacy of long-term absorbable (Maxon: polyglyconate) suture compared with standard absorbable (Prolene: polypropylene) in shouldice inguinal herniorrhaphy. It further aimed to revisit a standard method of repair and assess recurrence, particularly with reference to type of suture and grade of surgeon.
Method: Patients undergoing elective repair of inguinal hernia were randomized to have either non-absorbable (Prolene) or absorbable (Maxon) suture as part of a standard shouldice procedure. All operations, if not performed by a consultant surgeon, were done by a junior after a suitable period of instruction in the technique as used at this hospital. Most repairs were as day cases. All patients were followed up at 6 weeks, 6 months, 1 year and 5 years postoperatively to assess complication and recurrence rates.
Results: Almost 400 patients have been entered into the trial of whom 339 were available for the study. Mean age was 57·2 years, range 19–88. Most were men (327) and 62 (19 per cent) were smokers. Two hundred and twenty (64·9 per cent) were day patients; 170 operations were performed by a consultant, 130 by a registrar, five by a staff surgeon and 34 by a senior house officer. One hundred and sixty-two had Maxon while 177 had Prolene. So far, 301 patients (88·8 per cent), have been followed for at least 1 year. The complication rate has been acceptably low with wound pain on first outpatient visit being the most common problem (5 per cent). There have been five recurrences (1·4 per cent) but no differences between either suture. Grade of surgeon did not alter outcome.
Conclusion: Shouldice repair of inguinal hernia remains a very effective operation which can be performed as day cases with acceptably low complication and recurrence rates in a district hospital. Type of suture or grade of surgeon, once properly taught, did not adversely affect outcome in this study.

General 006

Cyclical or continuous peripheral parenteral nutrition: a 10-year review

R. Sowdi, M.D. Palmer, C.J. Mitchell and J. MacFie *Combined Gastroenterology Unit, Scarborough Hospital, Scarborough, North Yorkshire*

Background: Peripheral parenteral nutrition (PPN) is usually prescribed as a 24-h continuous infusion. However, cyclical administration may be associated with a reduced venous morbidity.
Method: Retrospective review of 10 years' nutritional practice in a district general hospital comparing morbidity of cyclical and continuous infusion of PPN.
Results: A total of 694 patients received PPN, as a continuous infusion in 455 (66 per cent) and cyclically over 12 h in 234 (34 per cent). Catheter-related sepsis occurred more frequently in the continuous than in the cyclical group (9·2 per cent versus 0·4 per cent, $P < 0{\cdot}02$). Phlebitis was twice as common in the continuous PPN group compared to cyclical infusion (5·9 per cent versus 2·8 per cent). Fluid overload occurred in 51 patients (7·3 per cent) in the series and was unrelated to infusion method. There were biochemical differences between the two groups.
Conclusion: Morbidity is higher with continuous infusion than with cyclical infusion. Cyclical infusion is the optimal method of giving PPN to gastroenterological patients.

General 007

The treatment of subungual melanoma with isolated limb perfusion: a 10-year experience

A.J. McKay, M.K. Lingam and R.M. MacKie* *Department of Surgery, Gartnavel General Hospital and *University Department of Dermatology, Western Infirmary, Glasgow*

Background: Subungual melanoma is rare and reports in the world literature of treating this condition with isolated limb perfusion (ILP) are limited. We present our 10-year experience of this condition.
Method: Thirty-two patients (14 men, 18 women) were treated with digital amputation and ILP using melphalan and mild hyperthermia. The disease was staged according to the M. D. Anderson Classification.

Results: Stage I (21 patients), stage IIIA (four patients), stage IIIB (three patients) and stage IIIAB (four patients) made up the study group. Nineteen lesions were on the foot and 13 on the hand. There was no operative mortality Of 21 patients with stage I disease, at mean follow-up of 46 months, 14 are alive and disease free and one is alive with disease. Five patients with stage I disease have died of disseminated disease and one was disease free at death from another cause However, the prognosis in stage III patients is poor, with only two survivors at 18 and 28 months.
Conclusion: It appears that ILP using melphalan and mild hyperthermia confers no additional survival benefit over appropriate surgery in stage I disease It does not significantly reduce disease-free suvival in stage III disease

General 008

A phase II evaluation of the Marlex plug hernia repair

R. Fisher, M. Hartley, J. Winstanley and G. Poston *Royal Liverpool University Hospitals, Broadgreen and Liverpool*

Background: Lichtenstein and laparoscopic inguinal hernia repairs, whilst an improvement on previous techniques, have associated postoperative pain, expense, and complications, including intraperitoneal trauma A new technique for inguinal and femoral herniae involves insertion of a Marlex plug into the hernial orifice, with a modified mesh overlay.
Method: Minimally invasive, through a 4 cm incision, and extraperitoneal, a Marlex plug requires non-periosteal absorbable stay sutures only A 7-month phase II trial was conducted on 40 patients (39 men, 1 woman, median age 64 years [range 26–90]).
Results:

Inguinal hernia	37 (24 indirect, 12 direct, 1 directo-indirect)
Femoral hernia	3
General anaesthetic	22
Local anaesthetic	17
Spinal anaesthetic	1
Median operation time (range)	35 (7–59) min
Median duration hospital stay (range)	24 (8–96) h
Median days until totally pain free (range)	6 (1–77) days
Median return to normal activity (range)	10 (1–84) days
Median return to work (range)	28 (3–56) days

Complications included three haematomas, conservatively managed and one failure of resolution of preoperative symptoms. There were no recurrences. Our results indicate that the plug repair is minimally invasive, quick, and gives excellent overall patient satisfaction
Conclusion: Patients are rapidly pain free, facilitating early return to normal activity. We believe a phase III randomized controlled trial of plug vs Lichtenstein repair is now needed.

General 009

How much do trainers train? An objective assessment

P.R Dikki, R.J. Aitken, S.J. Nixon and T.J. Crofts *Eastern General Hospital and Western General Hospital, Edinburgh*

Background: The aim of this study was to assess consultant supervision in general surgery.
Method: Details of trainee experience and consultant supervision for five general surgical operations performed under 17 consultants were retrieved from a prospective database
Results: Consultants assisted trainees in only a small proportion of the available operations. Supervision by individual consultants varied widely

		Consultant assisting		
Operation	No operations	Registrar [mean % (range)]	SHO [mean % (range)]	Unsupervised trainee [mean % (range)]
Inguinal hernia	740	6 (0–18%)	10 (0–52%)	50 (6–90%)
Varicose veins	719	10 (0–42%)	7 (0–28%)	40 (5–100%)
Right hemicolectomy	150	31 (0–52%)	3 (0–22%)	34 (0–100%)
Hartmann's	43	21 (0–60%)	0	23 (0–67%)
Laparoscopic cholecystectomy	552	27 (14–65%)	5 (0–17%)	28 (14–65%)

Conclusion: This study suggested many potential training opportunities were not used. The variation in consultant supervision suggests a minimal level of training should be defined

General 010

Corneal contamination during laparoscopic cholecystectomy

P.A. Super, J.M. Simms* and C.J. Stoddard *Royal Hallamshire Hospital, Sheffield, and *Chesterfield and North Derbyshire Royal Hospital, Chesterfield*

Background: This study aimed to assess whether contamination of the cornea during laparoscopic cholecystectomy may occur. Infective agents such as human immunodeficiency virus, hepatitis B and C have all been implicated in blood-borne transport from patients to medical staff, of these, hepatitis B has been documented as transmitted by corneal contamination in a non-surgical case.
Method: Protective glasses were worn by a single operator for 20 consecutive laparoscopic cholecystectomies. The length of procedure and awareness of operator to facial splashes was recorded before inspection of the lenses. The number of droplet splashes was counted at the end of the operation
Results:

Outcome (patients)	Mean droplets	Surgeon aware	Surgeon unaware
Splashes 14	4 2 (range 1–12)	1 operation	13 operations
No splashes 6			

Splashes over the glasses occurred in 14 operations (70 per cent). In those cases where splashes occurred there was a mean of four droplet marks (range 1–12) The operator was only aware of facial splashes in one patient (7 per cent) where splashes had occurred on the glasses.
Conclusion: There is a real risk of corneal contamination during laparoscopic cholecystectomy We recommend that surgeons and assisting theatre staff wear eye protection during all laparoscopic procedures.

General 011

Delays in emergency surgery: a prospective audit

E. Shah, P. Ogbue and H.M. Adair *The Ipswich Hospital NHS Trust, Ipswich*

Background: National Confidential Enquiry into Perioperative Deaths (NCEPOD) guidelines suggest that our provision of emergency surgical treatment needs to be improved The objective of this study was to assess the reasons behind delays in taking emergency surgical patients to theatre.
Method: A single surgical firm audited all its emergency operations over a 3-month period, the findings were discussed at the departmental audit meeting and changes in clinical practice implemented over the following 2 months The same firm then re-audited its emergency operations over a subsequent 3-month period Significant delay was defined as a time lapse of more than 2 h between the decision to operate and actual time of the patient entering theatre. Between the two audits, the surgical rota was altered so

that there was always a surgeon of appropriate grade available for emergency surgery. This surgeon was released from other commitments such as outpatient clinics and elective lists. The theatre manager made provision for a theatre dedicated to general surgery throughout the day to attend to emergencies and semi-emergencies only. The audit loop was closed.
Results: The total number of patients in the two analyses was 45 and 54, respectively. Initial audit revealed significant delay in 26 (58 per cent); the main reason being lack of theatre staff in nine (35 per cent) cases. Subsequent audit showed a delay in 30 (56 per cent), but theatre staff delays fell to six (20 per cent) cases. Initial figures indicated that 38 per cent of operations were done between 0900 and 1700 h, and this rose to 45 per cent on completing the audit cycle.
Conclusion: These are problems that beset most district general hospitals. Our study has shown that a dedicated emergency theatre team as well as co-operation between surgeons, anaesthetists and theatre staff can improve clinical standards.

General 012

The visceral slide technique for assessment of abdominal wound adhesions

S.G. Appleton, S.P.G. Padley* and J.N. Thompson *Departments of Surgery and *Radiology, Chelsea and Westminster Hospital, London*

Background: This study aimed to assess the role of the visceral slide technique in identifying intra-abdominal adhesions to the undersurface of abdominal wounds.
Method: The visceral slide technique has recently been described. Using a 7-MHz linear array ultrasound transducer the movement of the viscera directly beneath the abdominal wall is measured during exaggerated respiration. A slide of 2–5 cm of the viscera relative to the abdominal wall is considered normal, while a slide of 1 cm or less implies tethering of the viscera to the back of the abdominal wall and is strongly suggestive of adhesions.
Results: A total of 36 visceral slide ultrasound scans have been performed on 28 patients, of whom 18 had been referred for assessment of chronic abdominal pain attributed to adhesions. The remaining patients had laparotomies as part of a study into a new bioresorbable anti-adhesion membrane. Fifteen scans were performed preoperatively and 19 scans were performed postoperatively. The postoperative scans were performed at a mean of 6 weeks. Of the 15 preoperative scans, six suggested adhesions to the previous abdominal wound, five no adhesions present and in four the result was uncertain. The uncertain results were in wounds in the suprapubic region where the effects of exaggerated respiration are minimal. Eleven of these 15 patients went on to laparotomy and division of adhesions. In the seven patients with a definitive scan result, the visceral slide technique correctly identified the absence or presence of adhesions in five patients and was partially correct in two patients. There were 19 postoperative scans. Nine scans were performed in patients following laparotomy and division of adhesions. Eight out of the nine scans were negative for adhesions. The one patient with a positive adhesion scan after laparotomy was also the only patient to report a worsening of his symptoms.
Conclusion: The visceral slide technique is a reliable, quick and non-invasive method for assessing the presence of abdominal adhesions to the undersurface of previous laparotomy wounds. It also has a potential role in evaluating the effectiveness of adhesiolysis surgery.

General 013

24-hour access to a surgical database on CD-ROM has both educational and patient management benefits

C.J. Williams, K.J. O'Flynn and N.A. Scott *Department of Surgery, Hope Hospital, Salford*

Background: The aim of this study was to determine whether 24-h access to current surgical literature via a personal computer CD-ROM is of relevance to the junior surgeon managing acute surgical referrals.
Method: Over a 2-month period, a single basic surgical trainee assessed 53 acute surgical referrals. *Silver Platter* software was used to search the *Medline* database using one or two keywords for relevant information that would be of educational value and enhance patient management.
Results: Forty-nine per cent of database enquiries were made outside the hours 1700–0900. Thirty-eight per cent of all enquiries increased trainee knowledge and a further 17 per cent changed patient management. Forty-five per cent of searches did not reveal useful information. The most frequent enquiries regarded symptom aetiology (38 per cent), choice of antibiotics (19 per cent) and complications (19 per cent).
Conclusion: 24-h access to a surgical database on CD-ROM is a practical tool for the on-call basic surgical trainee and was found to have a large educational value together with a smaller but significant role in enhancing patient management.

General 014

Artificial neural networks for the prediction of recurrence of oesophagogastric junction cancers

J. Wayman, S. Dresner, R. Naguib*, S.A. Raimes and S.M. Griffin *The Oesophago-Gastric Cancer Unit and *Department of Electrical and Electronic Engineering, University of Newcastle upon Tyne, Newcastle upon Tyne*

Background: Identification of patients who are destined to suffer early recurrence, following radical surgical resection of cancer of the oesophago-gastric junction, is important to rationalize management decisions. We evaluate the ability of an artificial neural network to predict, using preoperative information alone, those patients destined to have recurrence within 1 year of surgery.
Method: Data from 103 patients undergoing potentially curative resection of adenocarcinoma of the oesophago-gastric junction were collected prospectively. A three-layer artificial neural network system was used. Preoperative data included gender, age, site of cancer, planned operative approach (two-stage Ivor–Lewis oesophagectomy, transhiatal, transabdominal gastrectomy with or without splenectomy or pancreatectomy) and grade of cancer from biopsy specimen were used as input variables. A separate network was designed for use with selected additional postoperative variables including depth of invasion, neural invasion, vascular invasion, resection margin clearance, positive longitudinal resection lines, nodal status and total number of lymph node groups involved. Forty-three patients were used to train the network and 60 were used to test the system.
Results: Five patients in the test group developed recurrence. This was correctly predicted in all cases using preoperative data alone. Specificity was 60 per cent and accuracy 63 per cent. By including postoperative variables, sensitivity was maintained at 100 per cent but specificity and accuracy increased to 73 per cent and 75 per cent, respectively. There was a strong correlation between the predictive value of pre- and postoperative findings in individual patients (correlation coefficient = 0·6333: $P < 0 \cdot 0001$).
Conclusion: Artificial neural networks are able reliably to predict, even with limited clinical preoperative information, patients destined to fail when treated by surgery alone. This approach may have a role in assisting clinicians to achieve more appropriate selection of patients for surgery and neo-adjuvant therapy.

General 015

Neural networks as an aid in the diagnosis of acute appendicitis

P. Ziprin, S.W.T. Gould and G. Glazer *St Mary's Hospital, London*

Background: The aim of this study is to assess the effectiveness of a neural network in the diagnosis of acute appendicitis in patients presenting with right iliac fossa (RIF) pain.
Method: Retrospective data, with regards to age, sex, symptoms, signs and investigations as previously used in other scoring systems, of 15

patients with acute appendicitis and 15 patients with histologically normal appendices presenting with RIF pain were used to train the Weightless Advanced Neural Device. The symptoms, signs and investigations that were used were migratory RIF pain, nausea, anorexia, RIF tenderness, rebound tenderness, temperature, white cell count and differential. All patients had a preoperative diagnosis of acute appendicitis. The neural network was then tested with 20 further patients with a known diagnosis of a normal or an inflamed appendix with varying retinal coverage and number of neuronal inputs.

Results: The neural network was shown to have a 100 per cent specificity and sensitivity in the diagnosis of acute appendicitis using these data, which compares favourably with other diagnostic aids and scoring systems. These results were repeatable each time the network was built. It was shown that the neural network was able to reach the diagnosis with greater confidence when increasing numbers of neuronal inputs were used: confidence range with four neuronal inputs was 0–9 per cent and 3–30 per cent with eight inputs. Confidence was further improved with random neuron coverage when compared to horizontal coverage.

Conclusion: We have shown that this neural network can distinguish between patients with and without acute appendicitis presenting with RIF pain who underwent surgical exploration. Further evaluation will be required to determine if it can predict which patients presenting to the Accident and Emergency Department with acute RIF pain will require surgery.

General 016

Artificial neural networks for the prediction of outcome following surgery for gastric cancer

P.J. Drew, L. Bottaci, P. Magee, I.M.C. Macintyre, M.J. Kerin, J.R.T. Monson and G.S. Duthie *The University of Hull Academic Surgical Unit, Castle Hill Hospital, Hull & Western General Infirmary, Edinburgh*

Background: An artificial neural network (ANN) is a form of artifical intelligence that is able to learn non-linear relationships between data and use this knowledge to answer questions about further data to which it has not been exposed. We decided, therefore, to compare a neural network analysis with the traditional statistical approach for the prediction of outcome following surgery for gastric cancer.

Methods: ANNs were designed with 60 input variables in the first layer, 0, 2, 3, 4, 5, 6, 7, 15, 20, 25 or 30 hidden 'neurones' in the second layer and a simple positive negative output. Data from 183 patients were utilized: 133 to train and 50 to validate each ANN for the prediction of death at 12 months. The neural networks were then compared against traditional multivariate analysis on 10 randomly selected validation data sets.

Results: The ANNs achieved a mean sensitivity of 0.62 (range 0.61–0.65) and a specificity of 0.77 (range 0.73–0.79) with a mean overall accuracy of 0.71 (95% C.I. 0.57–0.83) as opposed to the traditional multivariate analysis which achieved a mean sensitivity of 0.56 (range 0.43–0.79) and specificity of 0.68, range 0.52–0.85 with a mean overall accuracy of 0.62 (95% C.I. 0.49–0.75). There was no statistically significant difference between the two methods of analysis although the ANNs were significantly more robust and consistent in their prediction.

Conclusion: The failure to improve on the accuracy of the traditional linear statistical methods may be due to either too small a learning set, too simple a problem or the absence of any underlying pattern in the data and further work is therefore required. This accepted, in practical terms, ANNs are able to provide a more consistent method of prediction of outcome gastric following gastric cancer surgery.

Vascular 032

The effect of intraoperative autologous leucodepletion upon leucocyte counts and levels of neutrophil activation

S.P. Cavanagh, A. Rawstron, M.J. Gough and S. Homer-Vanniasinkam *The Vascular Surgical Unit, The General Infirmary at Leeds, Leeds*

Background: Neutrophils (PMNs) are integral to the pathogenesis of ischaemia reperfusion injury (IRI) and PMN depletion by both mechanical and immunological methods has been shown to ameliorate this injury in animal models. A clinical assessment of these techniques has not been performed.
Method: In 10 patients undergoing limb salvage surgery, the effect of PMN depletion (using a double-lumen femoral venous catheter, extracorporeal circuit, leucocyte filter, and flow rates of 200 ml/min for 15 min [3000 ml or ~60 per cent blood volume filtered]) upon PMN, monocyte and lymphocyte counts, adhesion molecule expression (CD11b, CD18, L-selectin) and myeloperoxidase (MPO) levels was compared with changes in 10 control patients (CP) undergoing similar surgery. Samples were taken from both peripheral (PER) and femoral (FEM) venous blood at baseline and at reperfusion, 4 h, 24 h, 3 and 6 days (T_0, T_4, T_{24}, T_{3D}, T_{6D}).
Results: PMN were effectively depleted from the filtered blood from 4·04 × 10^9/L (range 2·55–5·75) [median and IQR] to 0·72 × 10^9/L (0·42–1·30) [P=0·002], and 1·08 × 10^9/L (0·10–1·89) [P=0·012] following 5 and 15 min of filtration, respectively. Monocyte counts also fell from 0·30 × 10^9/L (0·20–0·46) to 0·03 × 10^9/L (0–0·20) [P=0·004] at 5 min and 0·075 × 10^9/L (0·03–0·10) [P=0·09] at 15 min. Similarly lymphocyte counts were reduced from 1·45 × 10^9/L (1·09–1·9) to 0·1 × 10^9/L (0·08–0·22) at 5 min and 0·95 × 10^9/L (0·58–1·3) at 15 min (P<0·0001 at both points). PMN adhesion molecule expression was always lower in filtered patients (both FEM and PER), and was significant for CD11b at T_0 FEM (P<0·0001), T_4 PER (P=0·0195), T_{24} FEM (P=0·0012) and T_{3D} (P=0·0140). The reduction in CD18 expression was significant at T_0 PER (P<0·0001) and T_{24} FEM (P=0·0311), while falls in L-selectin were significant at T_4 PER (P=0·0072). Levels of MPO were higher in the filter group at T_0 FEM (P<0·0001) and T_4 FEM (P<0·0001).
Conclusion: This novel study of intraoperative PMN depletion shows a favourable reduction in activated neutrophils, that may ameliorate IRI. The incidence of infective complications, amputation and death were comparable between the two groups. In patients undergoing limb revascularization, this technique is safe, and the results suggest that further investigation is warranted.

Vascular 033

Vascular surgical intervention following complications of cardiovascular radiology: 13 years' experience in a single centre

D.R. Lewis, R.A. Bulbulia, C.D. Irvine, P. Murphy†, A. Jones†, F.C.T. Smith, R.N. Baird and P.M. Lamont *Departments of Surgery and †Radiology, Bristol Royal Infirmary, Bristol*

Background: This study investigates incidence and outcome of iatrogenic radiological vascular complications in a single vascular unit. Evolution of diagnostic and interventional cardiovascular radiology, along with introduction of non-surgical therapies for such complications, may have influenced the number of vascular complications requiring emergency surgery.
Method: Vascular surgical data were collated from information prospectively entered on computerized database and case-note review. Radiology data were collated from prospective entries in logbooks and a computerized database.
Results: A total of 24 033 cardiovascular radiological procedures were performed between 1984 and 1996 (61 per cent cardiac) with numbers increased annually. During this period 62 patients (40 peripheral; 22 cardiac) required emergency surgical intervention following radiological procedures. Mean (range) age was 62 (1–92) years, male to female ratio was 1:1. Number of cases requiring surgical intervention peaked in 1989 (0·7 per cent), subsequently reducing annually (0·18 per cent in 1996). Sites of vascular injury included common femoral artery (66 per cent), brachial artery (7 per cent), iliac artery (6 per cent), popliteal artery (4 per cent), other (17 per cent). Eighty-seven vascular surgical operations were performed (range 1–6 operations per patient). Interventions included thrombectomy/embolectomy (29), bypass grafting (16), direct repair (27). Seven major amputations were performed (two bilateral). Mortality following surgery was 9·7 per cent. Mean (range) inpatient hospital stay was 11·3 (0 to 75) days. A Poisson regression model indicated a 5 per cent reduction in risk for each successive year of observation, however, this did not reach statistical significance (P=0·16, 95 per cent CI 12 per cent decreased risk, 2 per cent increased risk).
Conclusion: The risk of surgical intervention following diagnostic or interventional cardiovascular radiology is diminishing. Surgical intervention is associated with a high risk of morbidity and mortality.

Vascular 034

How accurately recorded are OPCS codes for vascular surgery?

R.B. Galland, T.R. Magee, D.C. Berridge*, G.B. Hopkinson†, M.H. Lewis**, S. Shiralkar‡ and S.D. Parvin‡ *Bristol Royal Infirmary, Bristol, *St James Hospital, Leeds, †North Staffs Hospital, Stoke, **East Glamorgan Hospital and ‡Royal Bournemouth Hospital*

Background: Centrally recorded OPCS codes are based upon district returns. The aim of this study was to determine the accuracy of this system with regard to vascular surgery.
Method: Prospectively recorded audit data for vascular and endovascular procedures were compared with those obtained from the Department of Health and Welsh Office. Five UK hospitals were involved in the study. Data were obtained for the 12 months between April 1994 and March 1995.
Results: The total number of arterial reconstructions based on audit data was 648. Those recorded by the OPCS codes were 477. This represents a discrepancy of -26 per cent (range -13·1–63·8 per cent). When examining specific codes, similar discrepancies were seen. For example, in one hospital 38 AAA repairs were carried out but only two were centrally recorded. However, examination of ICD9 codes (relating to hospital admissions) for that hospital showed that 38 patients with AAA were admitted. A similar wide variation was seen when examining iliac and superficial femoral artery endovascular procedures. Despite the discrepancies of audit and OPCS data, broadly the codes did reflect the relative workload of the different hospitals.
Conclusion: This study shows that there is a marked underestimate of vascular workload when comparing central recorded data with that obtained from local audit. Marked variation is seen in the accuracy of data submitted from different hospitals.

Vascular 035

The impact of MRSA in vascular graft infections

I. Nyamekye, L. Phipp, R.A. Bulbulia, P.M. Lamont, R.N. Baird and F.C.T. Smith *The Vascular Unit, Bristol Royal Infirmary, Bristol*

Background: Methicillin-resistant *Staphylococcus aureus* (MRSA) has emerged as a significant pathogen because of resistance to current anti-

biotics. Our aim was to determine incidence of, and outcome after MRSA vascular graft infections in a single centre over 12 years.
Method: Patients undergoing arterial bypass procedures since January 1985 were identified from a computerized database. Case notes of patients with graft infections were analysed for potential risk factors. Limb and patient outcome were analysed with respect to primary operation, graft type and bacterial culture.
Results: A total of 2096 bypass operations were performed. Thirty-six graft infections occurred in 30 men and six women after a median of 8 months (range 10 days–7 years). Fifteen patients were operated on for claudication, 14 for critical ischaemia and seven for an aneurysm. Of 25 monocultures, seven were MRSA. MRSA also occurred in two patients as part of a mixed culture. The primary operations were 17 aortic, 10 infra-inguinal and nine extra-anatomic grafts. Eight patients had percutaneous transluminal angioplasty, 23 had dacron and five vein grafts. Death was most common after aortic graft infection (8/17) and dacron in graft infection (13/23), while amputation was more likely to follow infrainguinal infection (4/10) and vein graft infection (3/5). There were three deaths and three amputations in nine patients with MRSA infection compared to five deaths and two amputations in 12 patients with non-MRSA *staphylococcus aureus* infection.
Conclusion: MRSA is now a common cause of vascular graft infection in this hospital but the prognosis for life and limb is not worse compared to graft infections with non-MRSA bacteria.

Vascular 036

Randomized trial of rifampicin-bonded Dacron grafts for extra-anatomic vascular reconstruction: early results

B.D. Braithwaite, J.D. Beard, S. Darke, B. Davies, B.P. Heather, R.B. Galland, S. Parvin and J.J. Earnshaw *Gloucestershire Royal Hospital, on behalf of the Joint Vascular Research Group*

Background: Serious infection complicates a small proportion of prosthetic vascular grafts and usually follows implantation of bacteria at the time of graft insertion. The aim of this study was to determine whether the use of a rifampicin-bonded gelatin-coated Dacron graft (Gelsoft or Gelseal, Vascutek Ltd) could reduce the rate of infective complications after bypass.
Method: In a multi-centre study involving 14 vascular units, 257 patients underwent extra-anatomic bypass (femorofemoral 149; axillofemoral 80; cross iliofemoral 28) for claudication 46 per cent, ischaemic rest pain 28 per cent, gangrene 20 per cent or acute ischaemia 6 per cent. There were 178 men and 79 women, median age 69 years, range 43–92.
Results: One hundred and thirty-two patients (51 per cent) had no recognized risk factors for wound or graft sepsis; 82 (32 per cent) had one and 43 (17 per cent) two or more risk factors. Patients were randomized 1:1 using sealed envelopes to rifampicin bonding (1 mg/ml rifampicin soak for 15 min prior to insertion) or controls. Routine 3 shot antibiotic prophylaxis was administered according to local protocol. Follow-up is complete to 1 month. One hundred and twenty-three patients had rifampicin-bonded grafts and 134 were controls. No side-effects were noted from Rifampicin bonding. A total of 200 patients made an uncomplicated recovery [77 per cent bonded vs 78 per cent controls, $P = 0{\cdot}8287$ (χ^2 test)]. Median duration of hospital stay was similar in both groups: 10 days, range 1–79. There were 18 (7 per cent) perioperative deaths (9 per cent bonded vs 5 per cent controls, $P = 0{\cdot}2432$). There were two early graft infections (both in the unbonded group). Rifampicin-bonded grafts had the following advantages: reduced total incidence of wound complications, e.g. erythema/discharge/dehiscence (16 per cent vs 22 per cent, $P = 0{\cdot}2151$), reduced need for a post-operative course of antibiotics (13 per cent vs 18 per cent, $P = 0{\cdot}2788$) and fewer patients with delayed hospital discharge (7 per cent vs 11 per cent, $P = 0{\cdot}4077$).
Conclusions: Despite the fact that the main advantage of antibiotic bonding is expected to be a reduction in late graft infection, there were reductions in minor postoperative infective complications which alone may justify the (small) expense of rifampicin bonding.

Vascular 037

The surgical management of renal artery stenosis in children

R.T.A. Chalmers, A. Dhadwal, J. Deal*, M. Snell and J.H.N. Wolfe *Vascular Surgery Unit and *Department of Paediatric Medicine, St Mary's Hospital, London*

Background: The aim of this study was to assess the outcome of treating paediatric renovascular hypertension surgically.
Method: The study was a retrospective analysis of recent experience at one teaching hospital.
Results: There were nine young patients, median age 19 years (range 3–22). Presentation was asymptomatic hypertension (4), headache (3), claudication (1) and hypertensive encephalopathy (1). Initial median diastolic pressure was 100 mmHg (range 90–115); systolic pressure was 160 mmHg (range 130–185). Four had ECG changes of left ventricular hypertrophy. Arterial lesions were: isolated renal artery stenosis (6), mid-aortic syndrome (2), neurofibromatosis (1). Median time from diagnosis to treatment was 7 months (range 3–36). Balloon angioplasty was successful in one patient and failed in two. Operations performed included aorto-renal graft using saphenous vein/internal iliac artery/dacron (3), aorto-aortic graft with simultaneous renal revascularization by vein graft/direct reimplantation (2), spleno-renal bypass (1), renal autotransplantation (1). All patients were normotensive at discharge. Median follow-up was 2 years (range 2 months–11 years). Median time to stopping antihypertensive medication was 6 months (range 0–23). One patient needed secondary surgical intervention after 9 years for recurrent hypertension (patch to coeliac origin stenosis in patient with spleno-renal bypass). One 8-year-old girl with mid-aortic syndrome is currently awaiting surgery.
Conclusion: Renal revascularization for hypertension in the young patient is effective and durable. We advocate early intervention rather than waiting for systemic manifestations.

Vascular 038

The local delivery of rifampicin from a collagen carrier for the control of prosthetic infection

G.G. Kane, D. Brown and P.E. Watkins *Medical Countermeasures, CBD Porton Down, Salisbury, Wiltshire*

Background: The aim of this study was to evaluate the efficacy of locally delivered rifampicin in controlling experimental infection of prosthetic materials.
Method: Under general anaesthesia the carotid sheaths of six sheep were contaminated with 10^7 colony-forming units *Staphylococcus epidermidis*. Six hours later strips of sterile collagen (dry weight 0·5 g) were soaked in 1 ml of a 10 mg/ml solution of rifampicin. One strip was placed into each wound alongside sections of sterile Dacron and PTFE. Blood samples were taken up to 5 days after surgery (to measure rifampicin levels by means of a bacteriological inhibition assay) and wounds were re-explored at day 5 and day 14.
Results: Systemic levels of rifampicin were detected up until 24 h post-implantation with maximal systemic levels (mean 0·35 µg/ml) recorded between 6 and 12 h post-implantation. At day 5 wounds and graft material were bacteriologically sterile in 5 of 6 animals. At day 14, all wounds were sterile. Collagen removed at day 5 had detectable levels of rifampicin, but this was not present at day 14.
Conclusion: This method of drug delivery may be of value in surgical practice to allow a rapid and cost-effective method of providing local antibiotic delivery which also permits delivery of significant levels of systemic antibiotic.

Vascular 039

Popliteal artery entrapment syndrome: a collaborative experience

A.W. Lambert and D.C. Wilkins for the Joint Vascular Research Group *Department of Surgery, Derriford Hospital, Plymouth*

Background: Popliteal artery entrapment syndrome (PAES) is a rare condition that is probably under diagnosed. An extensive collective experience has been analysed to show the characteristics of presentation, together with preferred methods of investigation and management.
Method: Cases were collected from members of the Joint Vascular Research Group (10 centres comprise a population of approximately four million) during 1984–1995. Case notes were reviewed in detail.
Results: Twenty-one legs in seventeen patients were affected by the condition. There were fifteen men and two women. The mean age at presentation was 29 years (14–45 years). In one patient, no further information was available and this was therefore excluded from further analysis. The condition was bilateral in four patients in whom three legs were asymptomatic. At presentation, the duration of symptoms ranged from a few hours (acute leg ischaemia) to intermittent claudication of 6 years duration. Primary investigation included angiography (20), duplex (4), plain radiography (1) and MRI (1). There were two cases where thrombolysis was tried initially but failed. Seventeen legs had surgery and the primary procedures were as follows: popliteal artery release (PAR) alone (4), PAR together with thromboendarterectomy and vein patch (4), PAR together with vein patch (2), interposition vein graft (2), femoro-popliteal bypass (4) and thromboendarterectomy and excision of bony exotosis (1). There were two failed primary operative procedures; one femoropopliteal bypass and one interposition vein graft. No surgery was undertaken in three legs. In two of these, the popliteal artery was occluded but gave rise to minimal symptoms. In one case, the popliteal artery was patent and asymptomatic. No legs required amputation. Following surgery, 12 legs were asymptomatic and five had residual symptoms. Three legs have been lost to follow-up.
Conclusion: A diagnosis of PAES should be excluded in young patients presenting with intermittent calf claudication or acute limb ischaemia in the absence of trauma. Although in this series angiography was the most common investigation used to diagnose PAES, MRI has superseded this as it gives excellent anatomical definition of the structures within the popliteal fossa.

Vascular 040

Cyanoacrylate glue improves haemostasis of PTFE vascular anastomoses: a randomized prospective trial

T. Bhatti, S. Ashley, C. Cosgrove, A.J. Walker and D.C. Wilkins
Vascular Surgical Unit, Derriford Hospital, Plymouth

Background: This study aimed to determine if butyl-2 cyanoacrylate glue (Indermil$^{\text{TM}}$, Loctite Ltd. Dublin) can improve haemostasis of polytetrafluoroethylene (PTFE) vascular anastomoses by reducing stitch-hole bleeding.
Method: Twenty-three patients (7 men, 16 women, mean age 74 years) undergoing PTFE bypass from or to the common femoral artery (CFA) using 5/0 monofilament suture material were randomized to receive glue or no glue. The glue was applied as a sealant along the suture line at completion of the anastomosis to the CFA. On release of clamps, blood loss from the anastomoses and time to absolute haemostasis was measured.
Results: Two patients (both randomized to the glue group) were excluded due to technical defects in the anastomosis requiring additional sutures. The results were as follows:

	Mean blood loss (range)	Mean time to haemostasis (range)
No glue ($n = 11$)	169 ml (5–505 ml)	15 min 4 s (0–65 min)
Glue ($n = 10$)	12 ml (0–42 ml)	2 min 37 s (0–6 min 49 s)

Blood loss and haemostasis time were significantly less with glue ($P < 0{\cdot}01$, Mann–Whitney U-test).

Conclusion: Cyanoacrylate glue is a simple and inexpensive means of improving haemostasis of PTFE vascular anastomoses but does not compensate for technical imperfection.

Coloproctology 010

The outcome of surgical treatments for perineal sinus after proctectomy for Crohn's disease

T. Yamamoto, I.M. Bain, R.N. Allan and M.R.B. Keighley
Department of Surgery and Gastroenterology, Queen Elizabeth Hospital, Birmingham

Background: The aim of this study was to assess the outcome of surgical treatments for perineal sinus after proctectomy for Crohn's disease.

Method: The medical records of 14 patients who developed perineal sinus after proctectomy for Crohn's disease were reviewed.

Results: There were nine males and five females. The mean age was 33 (range 20–73) years. Perineal sinus occurred in 14 of 54 patients having proctectomy (26 per cent). So far 44 surgical attempts have been made to cure the sinus in these 14 patients: drainage alone (20), radical excision (20), gracilis transposition (2), rectus abdominis flap (2). The mean number of operations is three (±2) and total hospital stay per procedure is 18 (±26) days. In only three patients, the sinus has been resolved by radical excision and closure of the sinus after a mean follow-up of 45 (range 3–135) months. Gracilis transposition and rectus abdominis flap were not successful.

Conclusion: These data question the role of aggressive surgery for perineal sinus in Crohn's disease.

Coloproctology 011

Day surgery coloproctology: what do patients think?

T.A. Cook, M.W. Thompson-Fawcett and N.J. McC.Mortensen
Department of Colorectal Surgery, John Radcliffe Hospital, Oxford

Background: Increasing numbers of surgical procedures are performed on a day-case basis but colorectal surgical practice has been slow to embrace the concept due to perceived problems with postoperative pain management. The purpose of this study was to assess the reaction of patients to a newly instituted day surgery list dedicated to coloproctology.

Method: Over 1 year, 132 consecutive patients undergoing day-case general anaesthetic colorectal procedures were asked to complete a questionnaire on the first evening and 5 days after surgery. Minor and some intermediate procedures, including haemorrhoidectomy were performed as a daycase. All patients were discharged within 6 hours of operation.

Results: Questionnaires were completed by 105 patients (80 per cent), mean age = 44 (range 16–76) years, male:female = 58:47. Procedures performed were: haemorrhoidectomy (29), lateral sphincterotomy (17), fistula in ano (13), EUA ± biopsy (14), skin tags/warts (9), polyps (9), pilonidal sinus (8), mucosal prolapse (6). Pain scores diminished steadily over the 5 postoperative days. Seventy-six per cent felt postoperative pain was less than or the same as they had expected but 8 per cent thought it would have been reduced if they had stayed in hospital. Eighty-eight per cent had had a bowel action within 2 days. Eighteen per cent contacted their GP within 72 h, mainly because of bleeding, but only half of these required a visit. There were no readmissions. Ninety-two per cent felt they had received the right amount of information before surgery and 86 per cent were satisfied with information given afterwards. Only 11 per cent felt it would be more convenient to stay in hospital for 1–2 nights and 90 per cent would prefer a day-case procedure in the future.

Conclusion: Day surgery coloproctology can be performed safely with minimal impact on primary healthcare services. With appropriate explanation, day-case coloproctology has a high degree of patient acceptance.

Coloproctology 012

Colonic anastomoses: the price of failure

S.J. Wigmore, R.G. Wilson, D.W. Hamer-Hodges, D. Wright, K. Mealy, M.G. Dunlop and S.J. Nixon *University Department of Surgery, Western General Hospital, Edinburgh*

Background: This study aimed to investigate the mode of presentation and management of anastomotic failure following colonic anastomoses, to identify risk factors predisposing to this complication and to estimate the resultant resource implications.

Method: Anastomotic leaks occurred in 33 of 716 patients undergoing colonic anastomoses over a 6-year period (4·6 per cent) by computer search of all case records of patients admitted to the unit. A case control study was undertaken matching each index case with three controls (non-leak) by type and date of operation. Patients were deliberately not matched for age and sex to permit analysis of these variables.

Results: The median time of presentation of anastomotic failure was 7 days, however, classical symptoms of peritonitis, leukocytosis and pyrexia were absent in 40 per cent of patients. Operative management was required in 24 patients (18 immediate, six delayed) and nine were treated conservatively. Seventy-nine per cent of leaks occurred in patients undergoing left-sided colonic anastomoses. In these patients technical factors associated with anastomotic leaks included cross stapling of the rectal stump ($\chi^2=4{\cdot}23$, $P<0{\cdot}05$), and failure to use pelvic drains ($\chi^2=9{\cdot}7$, $P<0{\cdot}01$) or tetracycline lavage ($\chi^2=10{\cdot}5$, $P<0{\cdot}01$). Mortality was 39 per cent in patients with anastomotic leaks (3·1 per cent in case controls $\chi^2=29{\cdot}5$, $P<0{\cdot}001$). Of the survivors 8/20 were left with a permanent stoma ($\chi^2=32{\cdot}3$, $P<0{\cdot}001$ vs case controls) and 6/14 who had cancer developed local recurrence within 6 months ($\chi^2=7{\cdot}2$, $P<0{\cdot}01$ vs case controls). Patients who developed anastomotic leaks had a total median hospital stay of 36 days of which 4 were spent in ITU, required a median of 12 days of parenteral nutrition and had an estimated total cost of four times that of case controls ($P<0{\cdot}001$ Mann–Whitney U-test).

Conclusion: In this study technical factors associated with anastomotic failure included the use of cross stapling of the rectal stump and failure to use tetracycline lavage or pelvic drains. There are major resource implications arising from failure of colonic anastomoses and further research is required into the prediction of patients likely to develop leaks and into the understanding of the pathophysiology of anastomotic failure.

Coloproctology 013

A prospective trial of unstimulated graciloplasty in traumatic faecal incontinence

A.J.P. Eccersley and N.S. Williams *Academic Department of Surgery, Queen Mary and Westfield College, London*

Background: Faecal incontinence due to trauma can often be improved by direct sphincter repair, but if the sphincter defect is large or associated with pudendal neuropathy results are poor. We studied the effect of treating such cases with an (unstimulated) gracilis neosphincter with a view to later electrical stimulation if function was suboptimal.

Method: In a prospective trial 12 patients with intractable faecal incontinence of obstetric ($n=9$) or traumatic ($n=3$) aetiology underwent unstimulated gracilis neosphincter formation combined with simultaneous direct sphincter repair in nine. All had endosonographic sphincter defects greater than one third of the anal circumference, six had a bilateral neuropathy and previous sphincter repairs had failed in four. Patients were taught knee squeeze exercises to augment gracilis contraction and were evaluated with microballoon manometry and symptom questionnaires including Cleveland continence scores.

Results: At a median of seven (range 2–18) months after stoma closure, four patients report excellent bowel function (continence score <6/20). Six had moderate improvements of whom one was further helped by subsequent implantation of a neural electrical stimulator. Three encountered evacuatory difficulties precluding electrostimulation. Perineal sepsis prevented stoma reversal in two.

	Median continence score (range)	Median resting pressure (range)	Median squeeze pressure (range)
Pre-gracilis	18 (14–20)	30 (15–70) cmH$_2$O	46 (30–100) cmH$_2$O
Post-gracilis	13 (2–20)	40 (10–70) cmH$_2$O	60 (20–100) cmH$_2$O
Significance (Wilcoxon)	0·012	0·07 (NS)	0·04

Conclusions: The unstimulated gracilis neosphincter can restore continence when direct repairs alone are likely to fail. Later electrostimulation can further improve those with moderate function provided there is no significant evacuatory difficulty.

Coloproctology 014

Colonic lesions demonstrated by magnetic resonance imaging using intraluminal gadolinium contrast

S.W.T. Gould, G. Lamb, N. Vaughan, A. Wan, W. Gedroyc and A. Darzi *Academic Surgical Unit, Imperial College School of Medicine at St Mary's and Centre for Biological and Medical Systems, Imperial College, London, UK*

Background: Interventional magnetic resonance (MR) machines now allow image-guided colorectal surgery. The aim of this study was to develop imaging techniques for the human colon which are able to detect intraluminal pathology and visualize lymph nodes as a preliminary procedure to MR-guided surgery.
Method: Seven resected colon specimens were studied in a 0·5 T General Electric Signa SP10 Interventional MR machine. There were four right hemicolectomy, one sigmoid and one rectal specimen from segmental resections for carcinoma. There was one specimen from a subtotal colectomy for Crohn's colitis with macroscopic pseudopolyposis. Static imaging [T1/T2 fast spin echo (FSE) and fast gradient recalled (FSPGR), acquisition times 6–90 s] was performed in the head coil in all three orthogonal planes. This was repeated after filling the colonic lumen with a solution of 1 per cent Gadolinium-DTPA (Gd) in water. All specimens were examined in routine histological fashion. Images were interpreted by a radiologist unaware of the histology result and an estimate made of the depth of penetration of the tumours through the colonic wall.
Results: Imaging without intraluminal contrast demonstrated the tumour as a localized thickening of the colonic wall in all six cases but gave little definition of the intraluminal part of the lesion. The wall of the Crohn's colon was clearly abnormally thickened. However, intraluminal contrast delineated clearly the tumours and also identified correctly two further adenomas in one specimen. Pseudopolyps were demonstrated in the Crohn's bowel. Coronal images yielded the greatest information. Mesenteric lymph nodes were easily seen in all specimens. Penetration of tumour into subserosal fat was demonstrated in three cases and a deposit in the extraperitoneal fat in one. These findings were in accordance with those from a histological examination.
Conclusion: MR imaging of the colon using a Gd solution clearly demonstrates space occupying lesions *in vitro*, with scan times short enough to be potentially used *in vivo* and also appears accurate enough to predict depth of invasion through the bowel wall. Further assessment of the technique *in vivo* may now be performed.

Coloproctology 015

Video-rigid sigmoidoscopy versus conventional sigmoidoscopy: a controlled randomized study

N.J. Taffinder, S.W.T. Gould, A.C.T. Wan, P. Taylor and A. Darzi *Academic Surgical Unit, Imperial College School of Medicine at St Mary's Hospital, London*

Background: This study aimed to assess the efficacy of a novel fine-bore video-rigid sigmoidoscope (VRS) and compare examination length and patient discomfort to conventional rigid sigmoidoscopy (CRS).
Method: The VRS is connected to a monitor and provides video magnified images of the rectum. It is significantly longer than the CRS (30 vs 22 cm) and thinner (10 vs 20 mm). Air can be insufflated by hand through the tip of the scope and the lens is kept clean by a dedicated wash channel. Fifty-eight patients attending a rectal outpatient clinic were enrolled for the study and all were examined with both the CRS and VRS in a random order. The examinations were performed by one of three surgeons with a colorectal nurse practitioner. Length of insertion and visual analogue discomfort scores were recorded by the person performing the examination. The VRS examinations were recorded on video or still pictures for documentation in the notes. Significant pathology was referred for full colonoscopy where appropriate. Ethical approval was obtained for the study.
Results:

Results (mean = SD)	Pain scores (visual analogue)	Examination distance (cm from anal verge)
Video sigmoidoscope	3·0 = 1·8*	23·2 = 5·9*
Conventional sigmoidoscope	5·5 = 2·7*	16·5 = 3·8*

Wilcoxon signed rank test: *$P<0{\cdot}001$.

Conclusion: The VRS was associated with a significant reduction in patient discomfort and a more thorough examination of the rectum and rectosigmoid. The quality of visualization obtained by the VRS was subjectively far superior, and in addition the examination could be recorded for permanent documentation.

Coloproctology 016

Early detection of colorectal cancer using fluorescence

M.A. Jahan, I.S. Tait, E.L. Newman and A. Cuschieri *Department of Surgery, Ninewells Hospital and Medical School, Dundee*

Background: Delta-aminolaevulinic acid (5-ALA) is metabolized to the fluorescent photosensitizer protoporphyrin IX (PpIX), which accumulates in tumour tissues, and thus can be used to enhance early detection of cancer and dysplasia by tumour-specific fluorescence. Fluorescence diagnosis (FD) may have potential to enhance endoscopic detection of precancerous and malignant lesions in the colon, e.g. polyps, ulcerative colitis and familial adenomatous polyposis, but has not previously been evaluated in the lower gastrointestinal tract. Therefore, the aim of this study was to evaluate fluorescence patterns in colorectal carcinomas after oral ALA administration to determine whether FD can be applied to the lower gastrointestinal tract.
Method: Fifteen patients with histologically confirmed colorectal carcinoma (8 rectal, 3 right colon, 1 transverse colon, 3 left colon) received an oral dose of ALA (20 or 40 mg/kg) 4–6 h before surgery. Colonic/rectal specimens were evaluated immediately after resection. Tumour PpIX fluorescence was induced by exposure to blue light (380–410 nm), and all fluorescent areas within resection specimens biopsied and correlated with tissue histology (gold standard). Normal colonic and rectal mucosa adjacent to the macroscopic tumour was also exposed to blue light, and fluorescent areas biopsied (controls).
Results: Spectroscopic analysis of the tumour fluorescence confirmed tissue conversion of ALA to PpIX, with spectral emission peaks identified at 630, 680 and 710 nm. Sixty-two biopsies were obtained from fluorescent and non-fluorescent mucosa (macroscopic normal $n=33$, macroscopic abnormal (cancer) $n=29$). All non-fluorescent macroscopic normal areas had confirmed benign histology ($n=33$; 100 per cent), whereas 24/29 (83 per cent) fluorescent areas contained histology confirmed invasive adenocarcinoma. Based on this small study, the sensitivity and specificity of FD for predicting invasive colonic cancer were 83 per cent and 100 per cent, respectively. No adverse side-effects were documented at this dose of ALA, other than a transient elevation of liver transaminases (48 h).
Conclusion: ALA-induced tissue fluorescence can discriminate between normal mucosa and neoplastic colorectal lesions when studied *ex vivo*. This preliminary study suggests that ALA-induced FD has a potential role for endoscopic surveillance of patients at high risk of developing colorectal cancer.

Coloproctology 017

Analysis of 10 000 colonoscopies at a district general hospital with a dedicated endoscopy service

K.P. Harris, G. McLeod and C.G. Marks *Department of General Surgery, The Royal Surrey County Hospital, Guildford, Surrey*

Background: The Endoscopy Section Committee of the British Society of Gastroenterology (1987) presented guidelines for colonoscopy services, suggesting that 161 colonoscopies per 100 000 population per year should be the minimum ideal provision. We present data derived from 7 years' experience of a dedicated endoscopy unit, of a district general hospital, serving a population of 400 000.
Method: Data were derived from a computer database (Medical Systems Limited) of all endoscopic investigations performed between 1990 and 1996.
Results: A total of 10 165 colonoscopies were performed. The annual number performed each year increased over the 7 years from 1048 in 1990 to 1964 in 1996, representing 500 per 100 000 population. The indications for endoscopy were diagnostic (72 per cent), polyp follow-up (10 per cent), cancer follow-up (5 per cent), inflammatory bowel disease surveillance (6 per cent), haemoccult positive (4 per cent), and family history surveillance (2 per cent). Of the colonoscopies performed, 1422 demonstrated polyps and 541 demonstrated cancers. Over the 7 years the diagnosis of polyps increased by 82 per cent, and that of cancers by 32 per cent. The percentage of normal colonoscopies remained stable over the period. Of the colonoscopies performed for the indication of polyp follow-up, 352 (35 per cent) demonstrated polyps, 19 (2 per cent) demonstrated cancers; of cancer follow-ups, 117 (21 per cent) demonstrated polyps, 24 (4 per cent) demonstrated cancers; of positive haemoccult tests, 80 (21 per cent) demonstrated polyps, 28 (7 per cent) demonstrated cancer; and of family histories, 26 (11 per cent) demonstrated polyps, and three (1 per cent) demonstrated cancer.
Conclusion: The increase in diagnosis of polyps and cancers over the period of study, associated with a stable rate of normal colonoscopies clearly demonstrates that the increase in number of colonoscopies performed is warranted; the significant number of positive findings from the follow-up and screening groups supports the inclusion of these indications in a department protocol. Careful consideration of duration of follow-up and follow-up interval is needed in order to avoid excessive investigation; in our series, the significant number of positive findings in those followed-up three and four times during the period of 7 years suggests that more frequent follow-up in a selected group of patients may be appropriate.

Coloproctology 018

Day case haemorrhoidectomy

A.J.G. Miles, A. Agombar and J.B.J. Fozard *The Royal Bournemouth Hospital, Bournemouth*

Background: Day-case haemorrhoidectomy is commonplace in many parts of the world but is not available at most hospitals in the UK. We have investigated the uptake and outcome of day-case haemorrhoidectomy in the first 2 years of providing the service at this hospital.
Method: Case-note review with completition of a standard proforma for all patients undergoing haemorrhoidectomy as a day case (same day admission and discharge) or as an in-patient over a 2-year period.
Results: Twenty-seven patients underwent successful day-case closed haemorrhoidectomy while 42 patients were treated as in-patients. One patient required emergency admission for faecal impaction after same-day discharge and one patient had a reactionary haemorrhage. None suffered acute urinary retention. Concomitant medical disease was the reason for exclusion from day-case haemorrhoidectomy in the majority of in-patients treated. Over 70 per cent of in-patients did not require postoperative opiate analgesia.
Conclusion: Closed haemorrhoidectomy with same-day discharge should be offered to all patients who require surgical treatment of haemorrhoids and do not have contra-indications to day surgery.

H&P 010

A pilot study of total enteral and parenteral nutritional support in patients with predicted severe acute pancreatitis

R. Gupta, K. Patel, A. Jackson, J.N. Primrose and C.D. Johnson
Southampton General Hospital, Southampton

Background: The aim of this study was to assess the safety of routine early total enteral nutritional (TEN) support in patients with severe acute pancreatitis (SAP). The efficacy of TEN on clinical, functional and psychological outcome variables was also studied.
Methods: Patients with SAP (APACHE II score ≥6 on admission) were randomized to receive total parenteral nutrition (TPN) ($n=8$) or TEN ($n=7$) on admission. Data relating to hospital stay, complications, and time to flatus and stool were recorded. Respiratory function was measured by vitalography and spirometry, muscle function by dynamometry, body fat by dual energy x-ray absorptiometry (DEXA), psychological state with the Hospital Anxiety and Depression scale and fatigue was measured using a visual analogue scale.
Results:

Variable	Feed	Admission	Day 3	Day 7
FEV_1 (L/s)	TPN	1·45 ± 0·45	1·33 ± 0·95	1·89 ± 1·26
	TEN	1·45 ± 0·46	1·64 ± 0·54	2·38 ± 0·50
PEFR (L/min)	TPN	273 ± 138	234 ± 167	331 ± 218
	TEN	330 ± 154	343 ± 101	445 ± 164
Grip (kg)	TPN	9 ± 4	12 ± 4	6 ± 5
	TEN	5 ± 4	5 ± 3	4 ± 4
Fat (DEXA-kg)	TPN	30 ± 13		32 ± 12
	TEN	25 ± 13		29 ± 10
Depression	TPN	9 ± 4	12 ± 4	6 ± 5
	TEN	5 ± 4	5 ± 3	4 ± 4
Fatigue (cm)	TPN	8 ± 1	8 ± 1	4 ± 2
	TEN	8 ± 1	4 ± 1	3 ± 2

All results are mean ± SD.

Patients were of similar age, APACHE II score and body mass index on entry to the study. None of the measured variables was statistically significantly different in the two groups on any of the study days although the TEN patients passed flatus more quickly (day 1 versus 4, $P = 0·04$).
Conclusion: This study has shown for the first time that TEN is safe and as efficacious as TPN in SAP.

H&P 011

Surgical treatment of non-functioning neuroendocrine tumours of the pancreas

V. Sharma, D. Al-Musawi and R.C.N. Williamson *Department of Surgery, Imperial College School of Medicine and Hammersmith Hospital, London*

Background: Approximately half the islet cell tumours of the pancreas fail to produce any biochemical 'syndrome'. The clinical and immunohistochemical features of these non-functioning neuroendocrine tumours are reviewed in a large personal series.
Method: Between 1982 and 1997, 51 patients (26 men, 25 women), median age 45 (range 15–76) years, were treated for a non-functioning neuroendocrine tumour. Patients presented with abdominal pain ($n=28$), obstructive jaundice (20), acute/chronic pancreatitis (17), weight loss (14), abdominal mass (13) and severe haemorrhage (8), while three asymptomatic tumours were diagnosed by ultrasound screening; two patients had multiple endocrine neoplasia type 1.
Results: Gut hormone profiles were normal except for four patients with raised serum levels of pancreatic polypeptide. Contrast-enhanced computed tomography and visceral angiography localized the tumour in 44 of 47 patients investigated, and all but five were highly vascular. Surgical treatment comprised 'curative' resection ($n=22$), palliative resection (16), bypass procedures (9) and biopsy alone (4). There were three postoperative deaths and 11 early complications. Of 36 tumours submitted to detailed immunostaining, 35 had more than two general neuroendocrine markers and 28 were clearly positive for one or more gut peptides. Actuarial cumulative survival (Kaplan–Meier product-limit method) was 57·4 ± 7·4 per cent (SE) at 5 years and 45·1 ± 9·8 per cent at 10 years. Patients undergoing curative resection had a survival advantage over those managed palliatively (70·3 ± 10·3 per cent vs 46·6 ± 10·1 per cent: $P=0·04$, log rank test).
Conclusion: Resection of these large hypervascular tumours can be a demanding technical exercise. Even with locally advanced disease, however, it offers an early survival advantage and may preclude an agonal bleed.

H&P 012

Rare pancreatic tumours

R.C.G. Russell and B.A. Theis *The Middlesex Hospital, London*

Background: This study aimed to review the presentation, operative course and progress of 98 patients with a rare pancreatic tumour who underwent surgery between 1977 and 1997. 'Rare' was defined as tumours that were not typical ductal or ampullary adenocarcinomas.
Method: The records of the patients were collected prospectively and follow-up was undertaken in a dedicated pancreatic clinic or by telephone by a specialist nurse. Data on presentation, operation, postoperative stay, complications and survival were recorded. The pathology was undertaken by a pathologist with an interest in pancreatic disease.
Results: Twenty-three patients presented with endocrine symptoms (insulinoma 22, gastrinoma 1); these patients had their tumour removed without mortality and all are alive or died without recurrence. Seventy-five patients presented either for diagnosis of pancreatic symptoms, on account of a very large mass, or as a differential diagnosis of a ductal carcinoma. These 75 tumours were treated by pancreatoduodenectomy ($n=38$), distal resection ($n=32$) and local excision ($n=5$). Three postoperative deaths occurred due to sepsis and haemorrhage (day 51), a pancreatic anastomotic leak and sepsis (day 47), and respiratory failure (day 25). The median length of stay was 12 days (range 7–42), and 25 patients had complications, two of whom required reoperation. The final histology was varied [neuroendocrine (29), cystadenoma (17), cystadenocarcinoma (7), mucin hypersecreting intraductal (7), hamartoma (3), hypernephroma (2), and 10 further miscellaneous malignant tumours]. At a median of 45 [range 1–240] months follow-up, 10/70 patients had died of recurrent disease (5/29 neuroendocrine, 2/2 hypernephroma and 3/8 miscellaneous malignant tumours).
Conclusion: The importance of identifying and treating these lesions is emphasized on account of their improved prognosis. Some of the larger tumours present a formidable technical operative undertaking, but the morbidity and mortality of the operation with its good outlook justifies the procedure.

H&P 013

The correlation between spiral computerized tomography (CT), endoscopic ultrasound and surgery in pancreatic and ampullary tumours

M.J. Midwinter, R.M. Charnley, C. Beveridge* and J. Wilsden
*HPB Surgery Unit, Freeman Hospital, Newcastle upon Tyne and *Department of Radiology, Newcastle General Hospital, Newcastle upon Tyne*

Background: The aim of this study was to examine the correlation between findings on spiral computerized tomography (CT) and endoscopic ultrasound (EUS) and surgery.

Method: Thirty-eight patients with pancreatic or ampullary tumours had spiral CT and EUS performed. Twenty-one were explored surgically with a view to resection. Findings from spiral CT and EUS were compared to findings at laparotomy.

Results: Seventeen of the 38 patients had very advanced disease or were unfit for surgery. Of 21 patients who had a laparotomy (17 pancreatic, four ampullary carcinoma) eight had resections and 13 had palliative bypasses performed. The tumour was identified by spiral CT in 67 per cent and EUS in 95 per cent of cases. Spiral CT failed to demonstrate five of the eight resectable tumours. EUS identified all of these.

	EUS sensitivity (%)	EUS specificity (%)	Spiral CT sensitivity (%)	Spiral CT specificity (%)
SMV/PV involvement	81	71	55	100
SMA involvement	25	100	50	100
LN metastasis	46	100	33	100

SMV/PV = superior mesenteric and portal vein; SMA = superior mesenteric artery; LN = lymph node.

Conclusion: EUS is better than spiral CT in demonstrating small, potentially resectable pancreatic and ampullary lesions. EUS is better than spiral CT in detecting SMV/PV involvement but the SMA is better evaluated by spiral CT. EUS may be more sensitive at demonstrating lymph node metastases.

H & P 014

Management of non-parasitic hepatic cysts: an evolving picture

A.J. McKinley, P. Holmes, E. Currie and O.J. Garden
University Department of Surgery, Royal Infirmary of Edinburgh, Edinburgh

Background: There is considerable debate as to the most effective management of symptomatic non-parasitic liver cysts. The aim of this study was to assess the evolution of surgical management with the advent of laparoscopic treatment, and to determine outcome for patients with simple cysts and adult polycystic liver disease (APLD).

Method: All patients surgically treated for liver cysts over a 9-year period were identified and case notes reviewed retrospectively to ascertain presenting symptoms and signs, investigations, surgical management and outcome. Simple cysts were defined as a single dominant cyst (± occasional small adjacent cysts) while polycystic lesions consisted of extensive multiple bilobar cysts. The latest patient contact was either in the clinic or via a telephone interview.

Results: Thirty-eight patients underwent 48 operations during the study period with a mean follow-up of 40 months. Twenty-three cases had simple cysts and 15 APLD, with seven (47 per cent) of the APLD patients having associated renal cysts. There was a marked female predominance, with over 90 per cent in each group. The simple cyst patients were older (mean age 62 years, range 33–84 years), compared to the APLD cases (51 years, range 39–79 years). All major symptoms were pressure related and included pain, fullness and nausea. The mean simple cyst diameter was 14·3 cm. Of the three surgical approaches employed (laparoscopic deroofing (20), open fenestration (14) and hepatic resection (14), the mean operation times were 94, 95 and 192 minutes, respectively with a mean postoperative stay of 3·5, 9 and 12 days. Seven of 14 hepatic resections required intraoperative blood transfusion. There was no mortality but postoperative morbidity included ascitic and bile leakage in addition to recognized postoperative complications. Twenty-three cases with simple cysts underwent a total of 26 operations. The laparoscopic group had a re-intervention rate of 8 per cent (1/13) compared to 29 per cent (2/7) for the open group. After hepatic resection no patient required re-operation. For the polycystic cases laparoscopic surgery was less successful with 5/7 (71 per cent) requiring re-operation, with one patient undergoing two subsequent operative procedures.

Conclusion: Laparoscopic deroofing has a potential role in the management of liver cysts in carefully selected cases but with a high re-intervention rate noted in polycystic disease, with posterior and central cysts accounting for most of the failures. An aggressive management approach appears justified in the management of symptomatic cysts to avoid further operative episodes but the overall outcome in APLD is less satisfactory.

H & P 015

An eicosapentaenoic acid-enriched nutritional supplement reverses cachexia in patients with advanced pancreatic cancer

M.D. Barber, J.A. Ross and K.C.H. Fearon *University Department of Surgery, Royal Infirmary of Edinburgh, Edinburgh*

Background: Conventional nutritional supplements do not affect the progress of cachexia in patients with advanced cancer. This study attempted to ascertain whether a nutritional supplement enriched with EPA could affect cachexia in patients with pancreatic cancer.

Method: Twenty patients with unresectable pancreatic cancer were asked to consume two cans of an EPA-enriched nutritional supplement daily in addition to their normal food intake. Each can contained 310 kcal, 16·1 g protein and 1·09 g EPA. Weight, body composition, dietary intake and resting energy expenditure (REE) were measured at baseline and after 3 weeks. Weight and body composition were measured monthly thereafter.

Results: Two patients experienced worsening or development of steatorrhoea. Otherwise no intervention-related adverse events were seen. Patients consumed a median of 1·9 cans/day. All patients were losing weight at baseline at a median rate of 3·3 kg/month (interquartile range 4·8–1·9). After administration of the EPA-enriched supplement patients had significant weight-gain at 3 (median 1 kg (range 0–2), $P = 0{\cdot}01$) and 7 weeks (median 2·5 kg (range 0·1–5·8), $P = 0{\cdot}03$). There was no change in percentage total body water suggesting weight-gain was not due to the accummulation of water. Analysis of body composition revealed a significant gain in lean body mass ($P = 0{\cdot}03$) and no change in fat mass after 3 weeks. Dietary intake increased from a median of 1319 kcal/day to 1635 kcal/day ($P = 0{\cdot}04$) and REE/kg lean body mass fell significantly ($P = 0{\cdot}02$).

Conclusions: In contrast to previous studies of conventional nutritional supplements in cancer patients losing weight, this study suggests that an EPA-enriched supplement may reverse cachexia in advanced pancreatic cancer. A randomized, placebo-controlled trial of this supplement is planned.

H & P 016

Judicious use of biliary stents in patients with difficult common bile duct stones is safe and effective

C.V.N. Cheruvu, J.W. Nunoo-Mensah, S. Singh and I.M. Paterson
Department of Surgery, Frimley Park Hospital, Frimley, Surrey

Background: The removal of common bile duct (CBD) stones difficult and associated with a morbidity rate of 10–15 per cent with mortality rates of 2–5 per cent. Biliary endoprosthesis are a simple, safe and effective method of treating patients with difficult CBD stones and this study reports our experience.

Method: Stents were inserted at endoscopic retrograde cholangiopancreatography (ERCP) in the following clinical situations: patients with jaundice or cholangitis in whom the duct was not cleared at the first attempt, unremovable large or impacted stones and the elderly, frail or uncooperative patient. The stent helped in the resolution of the acute crisis and allowed planning of subsequent strategy. There were three patient subgroups following stent insertion and they are: Group 1: long-term stent group; Group 2: staged endoscopic stone removal; and Group 3: open stone retrieval.

Results: Between November 1992 and July 1997, 70 patients with difficult CBD stones were stented as per the above criteria. All patients had prophylactic antibiotics and no patient had a coagulopathy. The study group comprised 25 men and 45 women, the median age was 78 (range 21–93 years). Seventy per cent of patients were >70 years and 43 per cent >80 years. In addition to age, 40 per cent had other significant co-morbidity. Attempted stent insertion was successful in every patient. These 70 patients underwent 161 ERCPs, 86 of which involved sphincterotomies. The results of treatment are shown below:

Treatment group	No. patients (%)	Median age	Co-morbidity	Morbidity	Mortality
1	20 (28·5%)	84·5	55%	1	1
2	42 (60·0%)	75·0	52%	4	0
3	8 (11·5%)	63·5	37%	1	0

The overall morbidity was 8·5 per cent, i.e. cholangitis = 4, bleeding = 1 requiring OGD and injection, pancreatitis = 1. One patient died (1·4 per cent) of sepsis 25 days poststent insertion. The mean follow-up was 28 (range 2–60) months and nine patients have died of unrelated causes.

Conclusion: We believe that insertion of an endoprosthesis at ERCP is a simple method of dealing with a difficult problem and our results show much lower incidence of complications and mortality than previously reported.

H&P 017

Normal HBA1C after pancreatic islet autotransplantation

S.A. White, A.C. Burden, C. Pollard, J.E. Davis, S.M. Swift, H.A. Clayton, N.J.M. London and A.R. Dennison *Department of Surgery, Leicester General Hospital, Leicester*

Background: Pancreatic islet autotransplantation (AT) combined with total pancreatectomy for chronic pancreatitis (CP) can prevent insulin independence, but not in all cases, a proportion of patients still require exogenous insulin. The aim of this study was to assess insulin secretion after a glucose challenge and general diabetic control in those patients with a functioning islet auto-graft.

Method: All patients received a 75 g oral glucose tolerance test. AT patients were compared to patients with CP either with normal ($n=15$) or impaired ($n=6$) glucose tolerance and non-diabetic patients (controls) without CP. In addition, HBA1C levels were also assessed but only in AT recipients and those having total pancreatectomy and those without an AT ($n=8$).

Results:

	C-Pep (pmol^{-1})	Glucose (0 min)* mmol^{-1}	Glucose (2 h) mmol^{-1}	Insulin (30 min) pmol^{-1}
Controls	663	3·5–5·5	<7·8	304
CP (normal GTT) $n=15$	663	4·3	4·5	387
CP (impaired GTT) $n=6$	467	7·1	10·7	101
AT $n=11$	444	7·9	17·5	144

*Fasting samples. All mean values.

Conclusion: Despite fasting, and 2 h hyperglycaemia with a reduced stimulated insulin response after a glucose challenge, AT recipients have significantly better glucose control as HbA1c levels were in the normal range (95 per cent c.i. 5–7·5) when compared to those patients having a total pancreatectomy without AT (955 c.i. 8·5–11·5). This suggests that *in vivo* insulin secretion, though not enough to achieve total insulin independence, is better than exogenous insulin therapy alone, in terms of achieving near normoglycaemia.

H&P 018

Is local and intraperitoneal instillation of bupivacaine after laparoscopic cholecystectomy effective for pain?

S.M. Ahmad, D. Hassanally, G. Harris and J. Simson *St Richard's Hospital, Chichester*

Background: In a prospective study we have tried to determine whether the use of bupivacaine is beneficial for pain relief following laparoscopic cholecystectomy. We have also tried to compare different methods of administration.

Method: Patients were randomized into four groups. Three treatment groups and one control. Treatment groups received 40 ml of 0·25 per cent bupivacaine. Group I was given bupivacaine by peri-portal infiltration, Group II by intra-peritoneal instillation, Group III by peri-portal infiltration (20 ml) and intraperitoneal instillation (20 ml) and Group IV was given 40 ml of normal saline (20 ml locally and 20 ml intraperitoneally). There were 10 patients in each group. All patients had same standard anaesthesia. Visual analogue pain scale was used to assess patients' pain 2, 4 and 24 h after surgery. All patients were given 100 mg of diclofinac suppository. They were also allowed coproxamol and morphine as required.

Results: The mean scores at 2 and 4 h after surgery were lower in all three treatment groups than in the control group although it was not statistically significant. The greatest effect was seen after 24 h after surgery in Group III mean 2·00 versus 4·25, $P<0·05$. Morphine requirements were significantly lower in the treatment group ($P=0·008$). Coproxamol usage was lower but not significant.

Conclusion: The numbers were small but this study does show bupivacaine is a useful adjunct for analgesia and is most efficacious when used in combination of local and intraperitoneal instillation.

Oestrogen receptor status strongly influences recommendations for adjuvant systemic therapy in higher risk breast cancer patients

G.C. Wishart[1], A.N. Harnett[2] and A.D. Purushotham[3]
[1]*Department of Surgery, Princess Royal Hospital, Haywards Heath,* [2]*Beatson Oncology Centre and* [3]*University Department of Surgery, Western Infirmary, Glasgow*

Background: The importance of oestrogen receptor (ER) status has been demonstrated in recent publications but it is still not available in many breast units throughout the UK. The aim of this study was to investigate the role that ER plays in the selection of adjuvant therapy in 100 consecutive patients with primary, operable, invasive breast cancer.

Method: Pathological prognostic indicators and recommended systemic therapy are recorded prospectively in all patients with breast cancer treated at the Western Infirmary. Following a 4-month period the histopathology of 100 consecutive cases was reviewed, including tumour type, size, grade, node status and lympho-vascular invasion but the ER status of each patient was blinded. A consensus plan for systemic therapy was then produced for each patient and compared with the original plan which had been decided on the basis of the above prognostic indicators but included ER status as well.

Results: Despite the absence of ER status it was still possible to predict current optimal adjuvant therapy (compared with the original recommendations) in the following groups: Group 1: >69 years, 18 of 20 patients (90 per cent); Group 2: postmenopausal, T1 N0 up to Grade 2, 14 of 14 patients (100 per cent); Group 3: patients eligible for BASO II study (T1, N0, Grade 1), 11 of 12 patients (92 per cent). In the remaining patients the absence of ER status resulted in inappropriate recommendations for adjuvant systemic therapy in 31 of 54 patients (57 per cent). Lack of ER status also influenced clinical trial accrual and in premenopausal patients contributed to a greater number being offered chemotherapy with no patients being randomized for ovarian ablation.

Conclusion: The availability of ER status strongly influences the prescription of adjuvant systemic therapy in patients with primary operable breast cancer. However, if a selective policy is used, which may be more cost-effective, all premenopausal patients and higher risk postmenopausal patients should have ER status performed.

Breast 011

Prospective assessment of early morbidity following axillary clearance for breast carcinoma

M. Duff, G. McGreal, S. Walsh, A. Hill, E. McDermott and N. O'Higgins *Department of Surgery, St Vincent's Hospital, Dublin*

Background: Axillary clearance is an accepted part of the assessment and management of patients with breast carcinoma, but is associated with morbidity, particularly arm swelling and limitation of shoulder movement. The aim of this study is to prospectively monitor patients for the development of these complications.

Method: We have studied 96 patients all of whom had level 1–3 axillary clearance. Measurements were taken preoperatively and at intervals postoperatively. Arm volume was measured using an optoelectronic volometer (Bosl Medizintechnic). Shoulder movements were measured with a goniometer.

Results:

Arm volume	No. patients	Mean ipsilateral volume (mean change, ml)	Mean contralateral volume (mean change, ml)	Swelling >200 ml (*n*)
Preoperative	96	1532 —	1520 —	0
2 days	93	1505 (−12)	1488 (−13)	0
5 days	92	1498 (−42)	1484 (−41)	0
3 months	37	1596 (+41)	1573 (+14)	3
6 months	40	1620 (+87)	1585 (+62)	3
1 year	15	1571 (+183)	1521 (+157)	1

Over the first postoperative week, the mean volume of both arms fell. No patient developed swelling of greater than 200 ml. Seven patients subsequently developed significant upper limb swelling. Swelling was detected at an early stage, and all were referred for physiotherapy. Two of these patients (28 per cent) had had wound infection compared to 12 per cent of those without swelling. There was no difference in the type of surgery performed, the number of nodes retrieved or the development of seromas between the two groups. Movements were expressed as a percentage of the preoperative values. Abduction, adduction and flection were severely impaired at day 5 after operation (68 per cent, 76 per cent, and 75 per cent, respectively). These had recovered almost fully by 6 months after operation (all >90 per cent of preoperative range). Extension and external rotation were not impaired.

Conclusion: The volometer was found to be a useful means of detecting arm swelling, so allowing early treatment. Shoulder function returns to normal in the majority of patients.

Breast 012

Neural networks are superior to the traditional prognostic indices for breast cancer patients

P.J. Drew, P. Magee*, L. Bottaci*, M. Menon, K. Heer, G.S. Duthie, J.N. Fox, P.J. Carleton, J.R.T. Monson and M.J. Kerin *The University of Hull Academic Surgical Unit, Castle Hill Hospital and *The University of Hull Department of Computer Science, Hull*

Background: An artificial neural network (ANN) is a form of artificial intelligence that is able to learn non-linear causal relationships between data sets and therefore has a theoretical advantage over the traditional linear statistical methods used in the construction of prognostic indices. We therefore compared the ability of ANNs to predict outcome in breast cancer with the established Nottingham prognostic index (NPI).

Method: Data on 460 patients collected retrospectively on the standard BASO database were used to train and validate the ANN. As with the NPI the size, grade and lymph node status were used as the input nodes with a variable number of neurones utilized in the hidden layer and a simple positive/negative output neurone. The ANN was trained to predict death at 1 year on 435 patients and then validated on data from 25 randomly selected patients which had been removed prior to training. The ANNs predictions were then compared to the patients' NPI group.

Result: The ANN achieved an overall accuracy of 84 per cent (95 per cent c.i. 0·70–0·98) for the prediction of death at 1 year. The positive predictive value of the network's predictions was 1·0 and the negative predictive value 0·83. In contrast, of the patients in the same validation set, 38 per cent of patients in the moderate-risk group were dead at 1 year as compared to only 33 per cent of patients in the high-risk group.

Conclusion: Artificial neural networks are able to predict outcome for breast cancer patients with greater accuracy than the traditional prognostic indices and particularly for the majority of patients in the 'moderate' risk group. Furthermore, ANNs can be trained on data available from a standard national database and could therefore be easily incorporated into such a programme in order to facilitate a prospective analysis.

Breast 013

Identification of genetic aberrations in breast tumours

R.L. Loveday, J. Greenman, P.J. Drew, J.R.T. Monson and M.J. Kerin *Department of Surgery, Academic Surgical Unit, University of Hull, Hull*

Background: The aims of this study were to use a novel cytogenetic technique, comparative genomic hybridization (CGH) to study genetic aberrations in breast cancer. CGH allows analysis of the entire genome for chromosomal deletions or amplifications in a single hybridization.
Method: CGH is based on the competitive hybridization of two differentially labelled DNA samples to normal metaphase spreads. Tumour DNA is labelled with a green fluorochrome and normal reference DNA is labelled with a red fluorochrome. Image analysis compares the intensity of the green to red staining and calculates the ratio thus allowing copy number changes to be identified throughout the genome. Twenty consecutive breast tumours were studied. All were staged according to standard TNM classification. Reference DNA was extracted from the patients lymphocytes and in order to distinguish between somatic and germline mutations the tumour specimens were also compared using standard reference DNA.
Results: Recurrent regions of amplification involved 1q (80 per cent), 3q (70 per cent), 5q (55 per cent), 12p (55 per cent) and 20p (70 per cent). The average number of amplifications per tumour was 12·5 ± 6·2, involving 8·2 ± 3·1 chromosomes in each tumour. Recurrent regions of deletion involved 17p (45 per cent) and 15p (45 per cent). The average number of deletions per chromosome was 10 ± 4·1, involving 5·3 ± 3·6 chromosomes in each tumour. The greatest number of aberrations (30) was found in a T4 tumour. The sites of most of the copy number changes were distinct from those of currently known cancer genes.
Conclusion: From this study it can be identified that there is a multigene involvement in breast carcinogenesis and that there are potentially a number of oncogenes or tumour suppressor genes involved in malignant progression which have not yet been identified. This has implications for future studies in breast cancer.

Breast 014

Recurrence of ductal carcinoma *in situ*: is wide local excision as safe as mastectomy?

A. Gandhi, P.A. Holland, W.F. Knox*, A.D. Baildam and N.J. Bundred *Departments of Surgery and *Pathology, University Hospital of South Manchester, Manchester*

Background: Wide local excision (WLE) is increasingly advocated for localized ductal carcinoma *in situ* (DCIS) lesions (<40 mm mammographic diameter) yet many studies show higher recurrence rates following WLE than following mastectomy. To determine the safety of WLE as a procedure for localized DCIS lesions, recurrence rates following WLE or mastectomy were compared.
Method: Clinical, radiological and histopathological data from a consecutive series of 284 women with confirmed DCIS (<40 mm diameter) presenting to one Breast Unit over a period of 23 years (1974–1996) were examined.
Results: Women were treated by WLE (n = 174, 60 per cent) or mastectomy (n = 114, 40 per cent). Incidence of comedo necrosis, microinvasion and high nuclear-grade tumours were similar in both groups of patients. Local relapse was defined as ipsilateral recurrence of *in situ* or invasive ductal carcinoma (see table). Sixty-six (39 per cent) women undergoing WLE have received adjuvant therapy [tamoxifen n = 41 (24 per cent), radiotherapy n = 19 (11 per cent), both tamoxifen and radiotherapy n = 6 (4 per cent)].

	Screen detected cases	Median size of lesion [mm] (range)	Local relapse	No. invasive recurrences
WLE n = 170	146 (86%)	12 (2·5–40)	20 (12%)	2 (10%)
Mastectomy n = 114	46 (40%)*	18 (2–40)*	7 (6%)**	3 (43%)

*P = <0·001, **P = not significant, statistics by χ^2 test.

Multivariate analysis revealed involved margin status to be the only significant predictor of local recurrence following WLE. Local relapse occurred in 13 of 53 (25 per cent) women with uncertain or involved biopsy margins and 7 of 117 (6 per cent) women in whom biopsy margins were clear of DCIS (P = 0·001).
Conclusion: Women with localized DCIS (<40 mm) may safely be offered WLE but it is essential that excision biopsy margins are clear of DCIS. If this criterion is achieved, relapse rates equal those seen following mastectomy.

Breast 015

Neoadjuvant chemotherapy for primary breast cancer: how many breasts are saved?

M.D. Bramley[1], C.R.M. Boggis[2], A.D. Baildam[1], A. Howell[3] and N.J. Bundred[1] *Departments of [1]Surgery and [2]Radiology, University Hospital of South Manchester, [3]Department of Medical Oncology, Christie Hospital NHS Trust, Withington, Manchester*

Background: Neoadjuvant chemotherapy is advocated in women with large primary breast cancers to improve the chances of breast conservation. The aim of this study was to assess clinical and mammographic response rates following primary chemotherapy for breast cancer, and relate this to mastectomy rates and mammographic predictors of response.
Method: A retrospective review of 95 women (97 tumours) receiving neoadjuvant combination chemotherapy for primary breast cancer was undertaken. The initial mean tumour diameter was 6·5 cm (± 2·1 cm). Ninety-two per cent of women had mammograms at diagnosis. The median postoperative follow-up was 20·5 (range 0–73 months).
Results: Overall, 77 per cent responded to chemotherapy but 52 per cent had a mastectomy. Non-responders had a significantly greater chance of mastectomy than responders (χ^2 = 5·9, P = 0·015). When pre-chemotherapy mammograms showed widespread microcalcification 13 out of 20 (65 per cent) failed to show a mammographic response to therapy ($P \leq 0·01$).

	Complete	Partial	Stable	Progressed
No. patients	29 (32%)	41 (45%)	17 (19%)	4 (4%)
Alive	26	28	11	2
Mastectomy	8 (28%)	23 (56%)	12 (71%)	4 (100%)
No. patients node positive	8 (28%)	22 (54%)	12 (71%)	3 (75%)

Conclusion: Although neoadjuvant chemotherapy obviates the need for mastectomy, the high rate of axillary nodal involvement (even in the complete responders) means that axillary node clearance is required. Widespread mammographic microcalcification (indicative of ductal carcinoma *in situ*) responds poorly to neoadjuvant chemotherapy, and is inappropriate in women who have these mammographic appearances at diagnosis.

Breast 016

Life insurance assessment for familial high risk and proven breast cancer patients

M.A. Steward and K. Horgan *The Breast Unit, General Infirmary at Leeds, Leeds*

Background: There is considerable confusion as to the insurability of women with either a high risk of developing breast cancer or who have had a previous diagnosis of breast cancer. The aim of this study was to seek clarification from the insurance industry on these points.
Method: A questionnaire was sent to all life insurance companies in the UK and registered with the ABI (Association of British Insurers). There were eighteen replies which included nine of the top 20 life insurance companies and also the most frequently used reinsurance company which influences 70 per cent of the UK reinsurance business.
Results: For known breast cancer patients 8 to 12 years has to elapse following treatment, before a woman is insurable, significantly axillary lymph node status is an essential component required in their assessment. Patient follow-up is expected and assumed to be conducted by appropriate clinicians. Involvement in clinical trials, which do not follow protocols similar to standard treatment, may affect a woman's ability to obtain life insurance. For high-risk patients, the use of genetic test results depends on the type of insurance required. For sums less than £100 000 the insurance industry has agreed, for the time being, not to use genetic information in their assessment. However, family history remains important and this information still needs to be declared, and for insurance sums greater than £100 000 the assessment is individualized and advice from reinsurance companies is sought. A negative genetic test will usually bring the premium loading back to normal.
Conclusion: Greater debate and discussion between breast cancer clinicians and life insurance companies is needed to allow a better mutual understanding of their practices. The interface between medicine and the insurance industry needs more clarity to ensure life insurance companies are kept well informed of the changes in clinical practice.

Breast 017

The management of patients with intermediate (AC3) cytology and a solitary breast lump: is a conservative approach safe?

B.J. Mander*, P.A. Beresford†, G. Tildsley†, T. Qureshi* and G.C. Wishart* **Departments of Surgey and †Histopathology, Princess Royal Hospital, Haywards Heath, West Sussex*

Background: The management of patients with AC3 cytology is controversial but in our unit excision biopsy has been routinely advised. We wished to review our policy to determine if a more conservative policy was safe.
Method: The records of all patients seen in the one-stop breast clinic with a discrete lump, who had a AC3 result on fine needle aspiration cytology (FNAC) over a 3-year period were reviewed. Clinical and mammographic findings at presentation were correlated with histopathological diagnosis.
Results: Between March 1994 and August 1997, 43 patients, median age 46 (range 21–72) years, had an intermediate FNAC result. Thirty-two patients underwent excision biopsy, two refused surgery and in five benign histology was obtained from trucut samples. The other four patients were treated conservatively and further cytology obtained at a later date, which was benign in all cases. Benign histology was obtained in 25 patients, eight patients had an underlying primary invasive breast cancer, two had a phylloides tumour and one had widespread ductal carcinoma *in situ*. All but two of the patients with underlying primary invasive breast cancer had associated abnormalities detected by clinical examination or on imaging. In the remaining two patients there was no clinical or mammographic suspicion of malignancy.
Conclusion: AC3 breast cytology must be taken seriously as it is frequently an indicator of underlying malignancy. The results of this study indicate that definite histology should be obtained in all patients because of the unacceptably high false-negative rate of clinical and radiological assessment in this group.

Breast 018

Impact of guidelines for general practitioners on fine needle aspiration of breast masses

S. Prance, L. Campbell, C. Teasdale and R.M. Watkins
Derriford Hospital, Plymouth

Background: Recent guidelines indicate that fine needle aspiration (FNA) by GPs is only acceptable in cases with recurrent breast cysts where the GP has the necessary skills. This study was designed to assess changes in GP practice as regards FNA since the introduction of these guidelines in November 1995.
Method: A retrospective review of 70 patients attending the breast clinic between May 1994 and July 1997, whose referral letter stated that they had recently undergone FNA by their GP, was performed. Twelve patients were in the group before guidelines were issued and 58 afterwards.
Results: Twenty-four patients had cysts aspirated by the GP. In the pre-guideline group all four patients had the fluid sent for cytological examination. Two needed further aspiration in clinic. After introduction of the guidelines, only 10 of 20 (50 per cent) had the fluid sent with nine out of 20 (45 per cent) needing further aspiration. Thirteen patients with a final diagnosis of carcinoma had undergone FNA by their GP. In the 1994–5 group all five patients had specimens sent for cytology. None was diagnostic of maligancy but three were suspicious. One was inadequate. In 1996–7, eight patients with malignancy had an FNA by their GP, but the specimen was not sent in six cases. The two sent were suspicious. Nineteen patients with benign breast change and no discrete mass had undergone FNA by their GP. Pre-guidelines there were two cases, both specimens were sent for cytology. Post-guidelines 17 patients had FNA and the specimen was not sent in 10.
Conclusion: Despite the guidelines, cyst fluid is still often sent unnecessarily and FNA is performed inappropriately and inaccurately by GPs.

Breast 019

Letrozole as primary medical therapy for locally advanced and large operable breast cancer

J.M. Dixon, C.D.B. Love, S. Tucker, C. Bellamy, R.C.F. Leonard and W.R. Miller *Edinburgh Breast Unit, Western General Hospital, Edinburgh*

Background: This study aimed to investigate the efficacy of letrozole given as primary systemic therapy and to compare responses with those obtained with tamoxifen in an identical clinical situation.
Method: Twenty-four patients were treated with letrozole (12 at 2·5 mg, 12 at 10 mg) and 65 patients were treated with tamoxifen. All were at similar stages $T_2 > 3$ cm, T_3, T_{4b}, N_{0-1}, M_0. All tumours were oestrogen-receptor (ER) positive (>20 fmol/mg cytosol protein or histoscore >80). Patients were monitored by monthly ultrasound and the change in volume over a 3-month period was calculated.
Results: The median percentage reduction in tumour volume with letrozole was 81, 95 per cent CI 69–86. Prior to letrozole 15 patients would have required mastectomy but after 3 months of therapy all were suitable for treatment by breast conservation. There was one complete pathological response and three patients had residual microscopic tumour foci only at the time of definitive surgery. In a series of 65 patients treated using an identical protocol with tamoxifen, the median percentage reduction in tumour volume was 48 (95 per cent, CI 27–48). Although not a randomized study this was a much lower reduction than that obtained by letrozole ($P < 0·005$).
Conclusion: Letrozole is highly effective when used as primary systemic therapy for large operable or locally advanced breast cancer and at least as good as tamoxifen in this setting.

Breast 020

Scintimammography in the assessment of local recurrence following conservative breast surgery

S. Tierney, H.M. Fenlon, N. Phelan, P. O'Sullivan, J.T. Ennis and T.F. Gorey *Institute of Radiological Science and Department of Surgery, University College Dublin and Mater Hospital, Dublin*

Background: Clinical assessment and mammography are unreliable in detecting local recurrence following conservative surgery for breast carcinoma. This study was designed to evaluate scintimammography (^{99m}Tc-Tetrofosmin) in determining malignancy in patients presenting with palpable masses who had previously undergone segmental mastectomy and radiotherapy for breast carcinoma.
Method: Eleven patients with suspected local recurrence following conservative breast surgery had scintimammography, plain film mammography and magnetic resonance (MR) mammography performed on the same day. The films were graded (benign or malignant) by a blinded radiologist before the lumps were diagnosed as benign or malignant based on histology (excision biopsy) or cytology (fine needle aspiration cytology). Four of the eleven patients (36 per cent) had recurrent breast carcinoma.
Results: ('+' indicates a positive (malignant) and '–' a negative (benign) test result).

		Plain film		MR mammogram		Scintimammogram	
	Histology	+	–	+	–	+	–
Malignant	4	2	2	3	1	4	0
Benign	7	0	5	1	6	0	7

Conventional mammography missed recurrent carcinoma in two patients and suggested recurrence in two others with postoperative fibrosis alone (negative predictive value 71 per cent). MR mammography correctly characterized seven lesions with one false-positive and one false-negative (negative predictive value 86 per cent). However, scintimammography correctly diagnosed all eleven patients (negative predictive value 100 per cent).
Conclusion: Scintimammography is inexpensive, acceptable to patients, uses equipment readily available in most hospitals, and is superior to conventional or MR mammography in the assessment of the previously operated and irradiated breast. We suggest that scintimammography should form part of the routine assessment of these patients.

Breast 021

Higher incidence of contralateral breast cancer in patients with a positive family history

H. Singhal, C.E. Potter and M.P. Osborne *Strang-Cornell Breast Center and Breast Service, Memorial Sloan-Kettering Cancer Center, New York*

Background: The identification of breast cancer susceptibility genes has increased the awareness of family history as a risk factor for breast cancer. The effects of a family history on presentation and pathology of breast cancer were the focus of this study.
Method: The records of patients undergoing modified radical mastectomy between 1979 and 1987 were reviewed. All patients with at least one first-degree relative with breast cancer were identified.
Results: A total of 1024 patients were identified, 171 (17 per cent) had a positive family history, there was no family history in 709 (70 per cent) and the status was unknown in 144 (14 per cent). Comparison of the patients with and without a family history showed no differences in mean age at presentation (55 versus 56 years), proportion of patients younger than 40 years (24 of 171 versus 76 of 701), predominant tumour type, multicentricity within the breast (35 of 171 versus 158 of 701) patients with T1 tumours (105 of 171 versus 447 of 701), axillary lymph node involvement (50 of 171 versus 215 of 701), oestrogen receptor status (82 versus 327) progesterone receptor status (40 versus 182). At a median follow-up of 83 months the incidence of contralateral breast cancer was higher in patients with a family history (10 compared to 17, χ^2 test, $P=0.03$). The median time to detection of the contralateral cancer was similar in both groups (43 months).
Conclusion: We conclude that patients with a family history of breast cancer do not have features at presentation or pathology that would merit a change in treatment strategy. However, the risk of contralateral cancer is increased.

Breast 022

Randomized controlled trial of the psychological effectiveness of multimedia computer counselling in symptomatic breast clinics

E. Street, P.J. Drew, S. Weaver*, J.R.T. Monson, G.S. Duthie, J.N. Fox and M.J. Kerin *The University of Hull Academic Surgical Unit and *The University of Hull Psychology Department, Castle Hill Hospital, Hull*

Background: More effective information transfer during counselling may help to reduce levels of anxiety in women attending symptomatic breast clinics. Multimedia has several theoretical advantages over the traditional leaflet-based approach and it was therefore decided to compare the psychological effectiveness of these two modalities.
Method: The multimedia counselling system was designed in our unit and evaluated in the clinical situation prior to the commencement of the prospective trial. A prospective randomized trial was then performed with patients from the symptomatic clinics being randomized to receive either traditional counselling or counselling with the multimedia system. The Speilberger State Trait Anxiety Scale was used to record psychological distress prior to the consultation, after being informed of the diagnosis and after counselling. In addition each patient was asked to complete a satisfaction questionnaire based on the Wolf Medical Interview Satisfaction Questionnaire.
Results: To date, 40 patients have been recruited: 18 were randomized to receive traditional counselling and 22 to receive multimedia counselling. There was no statistical difference in the levels of psychological distress between the two groups at any stage. However, a comparison of the satisfaction questionnaire showed that the patients found the counselling provided with the multimedia system superior to that provided by the traditional approach.
Conclusion: These preliminary results demonstrate that multimedia counselling is at least as psychologically effective as the traditional leaflet based approach and is preferred by the majority of patients. However, the advantages conferred by the use of multimedia counselling tools is such that they will undoubtedly become an essential counselling tool for use with patients with symptomatic breast disease.

Breast 023

Axillary sentinel node identification in breast cancer with dye injection alone

K. Horgan, B. Mancie-Jones, M. Madan, A. Andrew and C. Quinn *The Breast Unit, General Infirmary at Leeds, Leeds*

Background: Recent reports have suggested that identification and examination of the axillary 'sentinel' node can accurately determine axillary node status in breast cancer patients. Conventionally both radioisotope enhanced lymphoscintigraphy and peroperative blue dye injection are utilized to identify the sentinel node but this study examines the results of dye injection alone.

Method: Thirty-eight women with proven breast cancer (age range 35–86 years) had 4 ml Isosulfan blue colloid dye injected peritumourally after induction of anaesthesia. The sentinel node was identified as the most proximal node that was blue or the first axillary node encountered by a blue lymphatic and sent for separate histological study. All patients then proceeded to standard axillary dissection.

Results: Of the total of 38 patients, 14 had wide local excision and 24 mastectomy as their associated breast procedure. A total of 718 nodes were retrieved (mean = 19) and 19 axillae contained metastatic disease. A sentinel node was satisfactorily identified in 35 (92 per cent) as a blue node ($n = 18$) or the termination of a blue lymphatic ($n = 17$). There were three false-negative results for axillary nodal status (8 per cent) with overall sensitivity of 84 per cent. Patients treated by wide excision and separate axillary dissection were technically more difficult.

Conclusion: Sentinel node identification is a developing technology and is possible for a majority of patients using dye injection alone. The absolute accuracy and failure rate require further study after the learning curve is completed.

Breast 024

Evidence-based appraisal of the one-stop breast clinic

R. McCarthy, J. Baldwin, C. Fisher, H. Gajraj and D. Griffiths
Breast Department & Clinical Audit, East Somerset NHS Trust

Background: The assumption behind a focused one-stop clinic system is that rapid diagnosis and treatment leads to improved patient management. Based on our early experience of a one-stop breast clinic we set about testing this assumption.

Method: Patients with breast cancer diagnosed during a 6-month period of one-stop breast clinic (OSBC) (1/9/96–28/2/97) were retrospectively compared with patients diagnosed from a 6-month period of fast track clinic (FTC) (1/3/96–31/8/96).

Results: Thirty-one patients diagnosed with breast cancer via OSBC were compared with 41 patients diagnosed from FTC. We observed a decrease in the times from: a) referral to diagnosis (mean 3·4 versus 4·9 weeks); and b) referral to definitive surgery (mean 5·8 versus 7·3 weeks). The average number of visits per patient, prior to definitive treatment, in the OSBC was 1·2 compared to 2·0 in the FTC group. Thirty-nine per cent of patients attending the OSBC (12 of 31) versus 46 per cent of FTC patients had a diagnostic cytology (C5 fine needle aspiration). Four patients in each group required core biopsy (12·9 per cent, OSBC versus 9·7 per cent FTC). Forty-eight per cent of patients in the OSBC group (15 of 31) versus 44 per cent of patients in the FTC (18 of 41) required surgery for tissue diagnosis. Seven OSBC patients (22·5 per cent) had a frozen section biopsy, compared with three FTC patients (7·3 per cent).

Conclusion: The impact of OSBC has been variable and we believe the question "Is the one-stop clinic beneficial to the patient and is it cost effective", requires further appraisal and audit. Patient satisfaction will ultimately determine the continuation of this service, although the evidence that it has improved the clinical management of breast cancer remains to be proved.

Comparisons of stapled and sutured anastomosis following ileocolonic resection for Crohn's disease

T. Yamamoto, I.M. Bain, R.N. Allan and M.R.B. Keighley
Department of Surgery and Gastroenterology, Queen Elizabeth Hospital, Birmingham

Background: The aim of this study was to compare side-to-side stapled and standard end-to-end anastomosis following ileocolonic resection for Crohn's disease.
Method: One hundred and twelve patients requiring ileocolonic resection during the past 10 years have been reviewed.
Results: Forty patients had side-to-side stapled anastomosis (side-to-side staple line and both ends of bowels stapled transversely) and 72 underwent standard end-to-end sutured anastomosis. There were no complications related to anastomosis in the stapled group. The overall complication rate was 3 per cent in the stapled group compared with 25 per cent in the sutured group ($P=0{\cdot}005$). The overall recurrence rate at ileocolonic anastomosis was 1 of 40 (3 per cent) in the stapled group compared with 32 of 72 (44 per cent) in the sutured group ($P<0{\cdot}0001$). The overall reoperation rate for ileocolonic recurrence was 0 of 40 in the stapled group compared with 25 of 72 (35 per cent) in the sutured group ($P=0{\cdot}0003$). Using Kaplan–Meier methods, the cumulative recurrence and reoperation rates were lower in the stapled group compared with the sutured group ($P=0{\cdot}033$ and $P=0{\cdot}055$, respectively, log-rank test).
Conclusion: These data suggest that side-to-side stapled ileocolonic anastomosis for Crohn's disease is safer than sutured anastomosis and is associated with lower recurrence and reoperation rates.

Management of severe third-degree obstetric tears: a multidisciplinary approach

T.A. Cook[1], D. Keane[2] and N.J. McC. Mortensen[1] [1]*Departments of Colorectal Surgery and* [2]*Obstetrics and Gynaecology, John Radcliffe Hospital, Oxford*

Background: Sphincter injuries following vaginal delivery are often repaired by inexperienced junior staff who have a poor understanding of the anatomy of the anal sphincters with up to 50 per cent of women describing some degree of subsequent incontinence and 85 per cent of women having a sphincter defect detected by anal ultrasound. The purpose of this study was to assess the short-term impact of involving a colorectal team in the management of patients with complicated severe third-degree tears.
Method: Over a 1-year period four women (age 29–31) with severe third-degree tears extending into the anal canal or rectum were referred to the colorectal unit for repair of the injury. Two were repaired immediately and two following formation of a defunctioning colostomy. The internal anal sphincter (IAS) was identified and imbricated. A nerve stimulator was used to help identify the external anal sphincter (EAS) which was repaired using an overlapping technique. The women were reassessed at 3 months with anal manometry and anal ultrasound. Further clinical assessment was performed at 1 year following colostomy closure.
Results: Two women were primigravidae. Episiotomy was performed in two and one had a forceps-assisted delivery. Birthweights ranged from 3·3–4·6 kg. Anal ultrasound revealed intact EAS repairs in all four women although IAS was thinned anteriorly in one. Resting anal pressures were slightly low (range 40–56 cmH_2O) but satisfactory squeeze pressures were obtained in all four women (range 95–100 cmH_2O). At 1 year, three were continent to solids, liquids and flatus, incontinence score = 0 (after Miller), but one had occasional urgency. The fourth experienced occasional liquid seepage and frequent incontinence to flatus likely to represent IAS dysfunction (incontinence score = 7).
Conclusion: Satisfactory short-term results may be achieved following repair of severe third degree tears and a nerve stimulator is important in identifying viable EAS to be used in repair. An integrated approach involving the experience of the colorectal team and anorectal physiology permits planning of future deliveries and may improve the long-term outcome.

Colonic motility is abnormal before surgery for rectal prolapse

A.J. Brown, A.F. Horgan, J.H. Anderson, R.F. McKee and I.G. Finlay *Department of Coloproctology, Glasgow Royal Infirmary*

Background: Fixation rectopexy (FR) remains the operation of choice for rectal prolapse (RP), recurrence rates are low but the functional results are poor. We measured hindgut motility before FR to determine whether an underlying neuropathy would explain this.
Methods: Seven females (age 56·5 ± 9·7 years) had a multilumen catheter inserted in the colon before FR. Colonic intraluminal pressure was recorded for a mean of 19 ± 3 hours; the number of peaks over 5 and 50 mmHg, motility and high amplitude propagated contractions (HAPC) measured before and after a meal and compared with five controls.
Results:

	Patients (SD)	Controls (SD)
Pre-prandial		
Contractions >5 mmHg	119 (55)	44 (32) $P=0{\cdot}03$
Contractions >50 mmHg	3·5 (3·4)	0·2 (0·4)
Motility	504 (359)	101 (65) $P=0{\cdot}03$
Post-prandial		
Contractions >5 mmHg	117 (53)	133 (131)
Contractions >50 mmHg	8·2 (15·9)	1·2 (1·1)
Motility	224 (151)	153 (122)

Patients have high numbers of >5 mmHg contractions and motility before meals. Controls respond to meals by increasing motility unlike patients. HAPC were seen in one patient but all controls.
Conclusion: These data show that patients with RP have a hindgut motility abnormality prior to FR, similar to that observed in spinal cord injury. This may explain the poor functional results after surgery offering a rational for colonic resection.

Coloproctology 022

Preliminary experience with coil embolization for major colonic haemorrhage

J.E. Hartley, A.A. Nicholson, I. Curzon, D.F. Ettles, P.W.R. Lee, G.S. Duthie and J.R.T. Monson *The University of Hull, Academic Surgical Unit, Cottingham, East Yorkshire*

Background: Although most patients with colonic bleeding settle with conservative measures, a proportion require emergency surgery which is associated with high morbidity and mortality. This study aimed to determine the safety and efficacy of coil embolization for the control of major colonic bleeding.
Method: Nine consecutive high-risk patients (three men, six women, mean age 81, range 72–87 years) with major colonic bleeding have undergone coil embolization. All had failed to respond to conservative measures (mean Hb at angiography 6·3 g despite mean transfusion volume of

6 units), were haemodynamically unstable at the time of angiography (mean systolic pressure 85 mmHg), and were destined for emergent laparotomy should embolization fail.
Results: In eight patients embolization achieved rapid haemostasis, with only one of these requiring further intervention for bleeding. Two of the eight subsequently developed ischaemic complications which were successfully managed conservatively. The ninth patient with Crohn's colitis required emergency surgery for continued haemorrhage, despite embolization of multiple left colonic bleeding points, and subsequently died
Conclusion: This experience demonstrates a role for coil embolization in the management of colonic bleeding where significant ischaemia is unlikely, provided the marginal artery is preserved. The use of these techniques in selected groups of patients can obviate the requirement for emergency surgery.

Prolonged delayed healing pilonidal sinus wounds can be avoided

T.G. Allen-Mersh, H. Patel, M. Lee and I. Bloom *Department of Gastrointestinal Surgery, Imperial College School of Medicine, Chelsea and Westminster Hospital, London*

Background: The aim of this study was to determine whether excision with primary closure of pilonidal sinus by a surgeon with a special interest could abolish delayed healing.
Method: We compared inpatient stay and time to healing in 102 pilonidal sinus patients treated by either wide skin excision and asymmetric primary closure (Karydakis procedure) carried out by one surgeon or laying open. Follow-up was from outpatient clinic records, and patient and GP questionnaires.
Results:

	Primary closure ($n=50$)	Lay open ($n=52$)	*P* value
Hospital stay (days) median (IQR)	7 (6–8)	2 (1–2)	Mann–Witney U-test <0·0001
Interval from operation to cessation of dressings (weeks) median (IQR)	3 (3–6)	6 (4–8)	Log rank <0·0003
No. patients unhealed at 10 weeks from operation	0	10	χ^2 0·003
No. recurrences	0	5	χ^2 0·073

Conclusion: Excision with primary closure resulted in a shorter period with dressings and fewer unhealed wounds, but involved a longer hospital stay compared with laying open. Prolonged delayed healing pilonidal sinus wounds can be avoided, however, as the Karydakis approach involved greater hospital cost and consultant input, patient selection becomes important and criteria for this need to be developed.

Transanal resection for rectal carcinoma

T. Theodosopoulos, B.D. George, N. Mortensen and M. Kettlewell *Department of Colo-Rectal Surgery, John Radcliffe Hospital, Oxford*

Background: A minimally invasive approach to rectal carcinomas may be appropriate for frail patients and those with advanced disease. Transanal resection (TAR) utilizes a modified urological resectoscope to resect rectal tumours.
